Pertussis should be suspected in any individual who has pure or predominant complaint of cough, especially if the following are absent: fever, malaise or myalgia, exanthem or enanthem, sore throat, hoarseness, tachypnea, wheezes, and rales. For sporadic cases, a clinical case definition of cough of =14 days' duration with at least one associated symptom of paroxysms, whoop, or post-tussive vomiting has sensitivity of 81% and specificity of 58% for culture confirmation. Approximately 20% of university students who have been studied on many continents, who had no known contact with pertussis and had coughing illness for >7 days, had pertussis. Apnea or cyanosis (before appreciation of cough) is a clue in infants <3 mo of age. *B. pertussis* is an occasional cause of sudden infant death.

Adenoviral infections are usually distinguishable by associated features, such as fever, sore throat, and conjunctivitis. *Mycoplasma* causes protracted episodic coughing, but patients usually have a history of fever, headache, and systemic symptoms at the onset of disease as well as frequent finding of rales on auscultation of the chest. Epidemics of *Mycoplasma* and *B. pertussis* in young adults can be difficult to distinguish on clinical grounds. Although pertussis is often included in the laboratory evaluation of young infants with “afebrile pneumonia,” *B. pertussis* is

associated uncommonly with staccato cough (breath with every cough), purulent conjunctivitis, tachypnea, rales or wheezes that typify infection due to *Chlamydia trachomatis*, or predominant lower respiratory tract signs that typify infection due to respiratory syncytial virus. Unless an infant with pertussis has secondary pneumonia (and is then ill appearing), the examination findings between paroxysms are entirely normal, including respiratory rate.

Leukocytosis (15,000–100,000 cells/mm^3) due to absolute lymphocytosis is characteristic in the catarrhal stage. Lymphocytes are of T- and B-cell origin and are normal small cells, rather than the large atypical lymphocytes seen with viral infections. Adults and partially immune children have less impressive lymphocytosis. Absolute increase in neutrophils suggests a different diagnosis or secondary bacterial infection. Eosinophilia is not a manifestation of pertussis. A severe course and death are correlated with extreme leukocytosis (median peak white cell count fatal vs nonfatal cases, 94 vs 18 $\times 10^9$ cells/L) and thrombocytosis (median peak platelet count fatal vs nonfatal cases, 782 vs 556 $\times 10^9$ /L). Mild hyperinsulinemia and reduced glycemic response to epinephrine have been demonstrated; hypoglycemia is reported only occasionally. The chest radiograph appearance is mildly abnormal in the majority of hospitalized infants, showing perihilar infiltrate or edema (sometimes

with a butterfly appearance) and variable atelectasis. Parenchymal consolidation suggests secondary bacterial infection. Pneumothorax, pneumomediastinum, and air in soft tissues can be seen occasionally.

All current methods for confirmation of infection due to *B. pertussis* have limitations in sensitivity, specificity, or practicality. Isolation of *B. pertussis* in culture remains the gold standard for diagnosis. Careful attention must be paid to specimen collection, transport, and isolation technique. The specimen is obtained by deep nasopharyngeal aspiration or by use of a flexible swab, preferably a Dacron or calcium alginate swab, held in the posterior nasopharynx for 15–30?sec (or until coughing). A 1.0% casamino acid liquid is acceptable for holding a specimen up to 2?hr; Stainer-Scholte broth or Regan-Lowe semisolid transport medium is used for longer periods, up to 4 days. Regan-Lowe charcoal agar with 10% horse blood and 5–40?µg/mL cephalexin or Stainer-Scholte media with cyclodextrin resins are the preferred isolation media. Cultures are incubated at 35–37℉ in humid environment (with or without 5% carbon dioxide) and examined daily for 7 days for slow-growing, tiny glistening colonies. Direct fluorescent antibody (DFA) testing of potential isolates using specific antibody for *B. pertussis* and *B. parapertussis* maximizes recovery. Direct testing of nasopharyngeal secretions by DFA is a rapid test, especially helpful in patients who have received antibiotics, but is reliable only in laboratories with continuous experience. Polymerase chain reaction (PCR) to test nasopharyngeal specimens has sensitivity similar to culture, averts difficulties of isolation, but is not standardized or available universally. DFA, culture, and PCR are all expected to be positive in unimmunized children during the catarrhal and paroxysmal stage of disease. Less than 10% of any of these tests is positive in partially or remotely immunized individuals tested in the paroxysmal stage. Serologic tests for detection of antibodies to various components of the organism in acute and convalescent samples are the most sensitive tests in immunized individuals and are useful epidemiologically. They are not generally available, are not helpful during acute illness, and are difficult to interpret in immunized individuals. Antibody to pertussis toxin elevated >2 standard deviations above mean of the immunized population is the most reliable result indicating recent infection.

Treatment.

Goals of therapy are to limit the number of paroxysms, to observe the severity of the cough, to provide assistance when necessary, and to maximize nutrition, rest, and recovery without sequelae (Box 180–1). Infants <3 mo of age are admitted to hospital almost without exception, as are those between 3–6 mo unless witnessed paroxysms are not severe, and those of any age if significant complications occur. Prematurely born young infants and children with underlying cardiac, pulmonary, muscular, or neurologic disorders have a high risk for severe disease.

Box 180-1. Caveats in Assessment and Care of Infants with Pertussis

- Infants with potentially fatal pertussis may appear well between episodes.
- A paroxysm must be witnessed before deciding between hospital and home care.
- Only analysis of carefully compiled cough record permits assessment of severity and progression of illness.
- Suctioning of nose, oropharynx, or trachea should not be performed on a "preventive" schedule.
- Feeding in the period following a paroxysm may be more successful than following napping.
- Family support begins at the time of hospitalization with empathy for the child's and family's experience to date, transfer of the burden of responsibility for the child's safety to the health care team, and delineation of assessments and treatments to be performed.
- Family education, recruitment as part of the team, and continued support after discharge are essential.

The specific, limited goals of hospitalization are to (1) assess progression of disease and likelihood of life-threatening events at peak of disease, (2) prevent or treat complications, and (3) educate parents in the natural history of the disease and in care that will be given at home. Heart rate, respiratory rate, and pulse oximetry are monitored continuously with alarm settings so that paroxysms can be witnessed and recorded by health care personnel. Detailed cough records and documentation of feeding, vomiting, and weight change provide data to assess severity. Typical paroxysms that are not life threatening have the following features: duration <45?sec; red but not blue color change; tachycardia, bradycardia (not <60 beats/min in infants), or oxygen desaturation that spontaneously resolves at the end of the paroxysm; whooping or strength for self-rescue at the end of the paroxysm; self-expectorated mucus plug; and post-tussive exhaustion but not unresponsiveness. Assessing the need to provide oxygen, stimulation, or suctioning requires skilled personnel who can document an infant's ability for self-rescue but who will intervene rapidly and expertly when necessary. Infants whose paroxysms repeatedly lead to life-threatening events despite passive delivery of oxygen or

whose fatigue leads to hypercarbia require intubation, paralysis, and ventilation. Subsequent management is complex, with frequent need to suction the airway and intervene when bradycardia or secondary pulmonary processes occur. Mist by tent, specifically avoided by some experts, can be useful in some infants with thick, tenacious secretions and excessively irritable airways. The benefit of a quiet, dimly lighted, undisturbed, comforting environment cannot be overestimated or forfeited in a desire to monitor and intervene. Feeding children with pertussis is challenging. The risk of precipitating cough by nipple feeding does not warrant nasogastric, nasojejunal, or parenteral alimentation in most infants. The composition or thickness of formula does not affect the quality of secretions, cough, or retention. Large-volume feedings are avoided.

Within 48–72?hr, the direction and severity of disease usually are obvious by analysis of recorded information. Many infants have marked improvement upon hospitalization and antibiotic therapy, especially if they are early in the course of disease or have been removed from aggravating environmental smoke, excessive stimulation, or a dry or polluting heat source. Hospital discharge is appropriate if over a 48-hr period disease severity is unchanged or diminished, no intervention is required during

paroxysms, nutrition is adequate, no complication has occurred, and parents are adequately prepared for care at home. Apnea and seizures occur in the incremental phase of illness and in those with complicated disease. Portable oxygen, monitoring, or suction apparatus should not be needed at home.

ANTIMICROBIAL AGENTS.

An antimicrobial agent is always given when pertussis is suspected or confirmed for potential clinical benefit and to limit the spread of infection. Erythromycin (40–50?mg/kg/24?hr divided qid PO; maximum: 2?g/24?hr) for 14 days is standard treatment. Limited studies of erythromycin salts dosed twice or three times a day for 14 days, erythromycin estolate (40?mg/kg/24?hr divided qid PO; maximum 1?g/24?hr) for 7 days, clarithromycin (15–20?mg/kg/ 24?hr divided bid PO; maximum 1?g/24?hr) for 7 days, and azithromycin (10?mg/kg/24?hr once a day PO) for 5 days have compared favorably with standard treatment for elimination of organisms. Their efficacy is unproved. Erythromycin resistance of *B. pertussis* has been reported rarely. Ampicillin, rifampin, and trimethoprim-sulfamethoxazole are modestly active, but first- and second-generation cephalosporins are not. In clinical studies, erythromycins are superior to amoxicillin for eradication of *B. pertussis* and are the only agents with proven efficacy.

A sevenfold to 10-fold relative risk for infantile hypertrophic pyloric stenosis (IHPS) has been reported in infants <6 wk of age treated with orally administered erythromycin. The highest risk appears to be in the first 2 wk of life in term infants, and with courses of =14 days. The risk of IHPS after treatment with azithromycin or clarithromycin is unknown. Physicians should inform families and weigh risks and benefits of prescribing macrolides in this age group. Alternative therapies are not well studied.

OTHER THERAPIES.

A handful of small clinical trials and reports suggest a modest reduction of symptoms from the β_2 -adrenergic stimulant salbutamol (albuterol). No rigorous clinical trial has demonstrated a beneficial effect; one small study showed no effect. Fussing associated with aerosol treatment triggers paroxysms. No randomized, blinded clinical trial of sufficient size has been performed to evaluate the usefulness of corticosteroids in the management of pertussis; their clinical use is not warranted. Intravenous use of a human hyperimmune pertussis immunoglobulin derived from immunizing adults is under investigation. Standard immunoglobulin for intramuscular or intravenous use is not recommended for treatment of pertussis.

ISOLATION.

Patients are placed in respiratory isolation for =5 days after initiation of erythromycin therapy. Children and staff with pertussis in child care facilities or schools should be excluded until erythromycin has been taken for 5 days.

CARE OF HOUSEHOLD AND OTHER CLOSE CONTACTS.

Erythromycin (40–50?mg/kg/24?hr divided qid PO; maximum 2?g/24?hr) for 14 days should be given promptly to all household contacts and other close contacts, such as those in daycare, regardless of age, history of immunization, or symptoms. Clarithromycin and azithromycin are potential but not proven alternative agents for those who cannot tolerate erythromycin. Visitation and movement of coughing family members in the hospital must be assiduously controlled until erythromycin has been taken for 5 days. Close contacts <7 yr of age who have received less than four doses of pertussis-containing vaccines should have vaccination initiated or continued to complete the recommended series. Children <7 yr of age who received a third dose >6 mo before exposure or a fourth dose =3 yr before exposure should receive a booster dose. If infection with *B. pertussis* is proved, the individual should complete the immunization series with at least diphtheria and tetanus toxoids; some experts recommend including the pertussis component as well. Antimicrobial prophylaxis is not routinely recommended for exposed health care workers. Coughing health care workers, with or without known exposure to pertussis, should be promptly evaluated for pertussis. For major hospital outbreaks, multifaceted control procedures have included targeted erythromycin treatment of coughing individuals, mass erythromycin prophylaxis, and immunization of adults.

Complications.

Rates of complications are difficult to establish because severe outcomes are preferentially reported, but infants <6 mo of age have excessive mortality and morbidity. Those <2 mo of age have the highest reported rates of pertussis-associated hospitalization (82%), pneumonia (25%), seizures (4%), encephalopathy (1%), and death (1%). Among 23 fatal cases in the United States in 1992–1993, approximately 80% were <6 mo of age. Preterm birth and young maternal age were significantly associated with fatal pertussis, and pneumonia

complicated >95% cases.

The principal complications of pertussis are apnea, secondary infections (such as otitis media and pneumonia), and physical sequelae of forceful coughing. The need for intensive care and artificial ventilation is usually limited to infants <3 mo. Apnea, cyanosis, and secondary bacterial pneumonia are events precipitating intubation and ventilation. Bacterial pneumonia or adult respiratory distress syndrome is the usual cause of death at any age; pulmonary hemorrhage has occurred in neonates. Fever, tachypnea or respiratory distress between paroxysms, and absolute neutrophilia are clues to pneumonia. Expected pathogens include *Staphylococcus aureus, S. pneumoniae*, and bacteria of oropharyngeal flora. Bronchiectasis has been reported rarely after pertussis. Children who have pertussis before the age of 2 yr may have abnormal pulmonary function into adulthood.

Increased intrathoracic and intra-abdominal pressure during coughing can result in conjunctival and scleral hemorrhages, petechiae on the upper body, epistaxis, hemorrhage in the central nervous system (CNS) and retina, pneumothorax and subcutaneous emphysema, and umbilical and inguinal hernias. Laceration of the lingual frenulum is not uncommon. Rectal prolapse, once reported as a frequent complication of pertussis, was probably due to pertussis in malnourished children or missed diagnosis of cystic fibrosis. It is distinctly unusual and should elicit evaluation for underlying condition. Especially in infants in developing countries, dehydration and malnutrition following post-tussive vomiting can have a severe impact. Tetany has been associated with profound post-tussive alkalosis.

CNS abnormalities occur at a relatively high frequency and are almost always a result of hypoxemia or hemorrhage associated with coughing or apnea in young infants. Apnea or bradycardia or both may result from apparent laryngospasm or vagal stimulation just before a coughing episode, from obstruction during an episode, or from hypoxemia following an episode. Lack of associated respiratory signs in some young infants with apnea raises the possibility of a primary effect of PT on the CNS. Seizures are usually a result of hypoxemia, but hyponatremia from excessive secretion of antidiuretic hormone during pneumonia can occur. The only neuropathology documented in humans is parenchymal hemorrhage and ischemic necrosis.

Prevention.

Universal immunization of children <7 yr of age with pertussis vaccine, beginning in infancy, is central to the control of pertussis (Chapter 282). Despite enormous effort, the critical mechanisms of immunity following disease or vaccination, a serologic correlate of protection, and the cause of vaccine-associated adverse events are not known. The only current standards for vaccine usefulness are clinical efficacy and safety. Current goals of immunization are protection of the individual from a significant coughing illness and control of endemic and epidemic disease.

ACELLULAR VACCINE.

Multiple diphtheria and tetanus toxoids combined with acellular pertussis (DTaP) vaccines currently are licensed in the United States and are preferred over those containing whole-cell pertussis (DTP) vaccines because of fewer adverse reactions. Recommendations for use of DTaP are similar to recommendations for use of DTP, which continues to be given to infants and children in many other countries. Acellular pertussis vaccines all contain inactivated PT and may

contain one or more other bacterial components (FHA, Pn, Fim 2 and 3). PT is detoxified either chemically or using molecular genetic techniques. Lacking serologic criteria for protection, licensure has been based on clinical efficacy trials conducted in Europe and Africa. Efficacy of licensed products to protect against severe pertussis can be considered similar, with relative protection against milder disease controversial. Mild local and systemic adverse events as well as more serious events (including high fever, persistent crying of =3?hr duration, hypotonic hyporesponsive episodes, and seizures) occur significantly less frequently among infants who receive DTaP compared with DTP vaccine. Whether the rare, potentially vaccine-associated events such as encephalopathy or anaphylactic shock will occur less frequently after acellular pertussis vaccine is not known.

DTaP containing vaccines can be administered simultaneously with any other vaccines used in standard schedules for children. Some products are licensed for use for all five doses. Combination of vaccines that include DTaP in place of DTP can affect immunogenicity of products. Combination vaccines should be used only in the dosing series and age group for which each is licensed, and when all components are indicated. When feasible, the same DTaP product is recommended for the first three doses of the vaccination series. Local reactions increase in rate and severity with successive doses of DTaP, although never reaching the magnitude of reactions following similar doses of DTP. Up to 2% of fourth and fifth doses of DTaP can be associated with entire limb swelling, with concurrent pain and erythema in approximately one half of children affected. Swelling subsides spontaneously without sequelae.

The same special considerations, precautions, contraindications, and reporting requirements for serious adverse events that exist for DTP vaccination apply to DTaP as well. Exempting children from pertussis immunization should be considered only in the narrow limits as recommended. Exemptors have been shown to have significantly increased risk for pertussis as well as a role in outbreaks of pertussis in immunized populations. Acellular pertussis vaccines are now licensed for use only among children through 6 yr of age. As studies of impact of pertussis in older individuals and trials of acellular pertussis vaccine in adolescents and adults accumulate, periodic reinforcing doses may be recommended.

Chapter 181 - *Salmonella*

Thomas G. Cleary

Salmonella infections occur worldwide. Acute enteritis, the most frequent presentation, is usually self-limited, although bacteremia and focal extraintestinal infections may develop, especially in immunocompromised patients. The latter group has become more important and complex because of the increasing number of children who are compromised by AIDS, organ transplantation, or chemotherapy. **Enteric fever**, or **typhoid fever**, is a severe systemic disease that is classically caused by *Salmonella* ser. Typhi (*Salmonella typhi*) and is found mainly in developing countries, but it is encountered worldwide because of international travel.

Molecular technology has enabled classification at the gene level. DNA analysis has proved that all *Salmonella* organisms are closely related genetically as a single species with six subgroups; most isolates causing human or animal disease belong to subgroup 1. The medical slang usage that treated each of the nearly 2,500 serotypes as though it were a separate species has fallen out of favor. The preferred designation currently is the abbreviated version of the formal name by the Centers for Disease Control and Prevention (CDC) (Table 181–1).

181.1 Nontyphoidal Salmonellosis

Etiology.

Salmonellae are motile, nonsporulating, nonencapsulated, gram-negative rods. Most strains ferment glucose, mannose, and mannitol to produce acid and gas, but they do not ferment lactose or sucrose. *S.* ser. Typhi does not produce gas. *Salmonella* organisms grow aerobically and are capable of facultative anaerobic growth. They are resistant to many physical agents but can be killed by heating to 130°F (54.4°C) for 1?hr or 140°F (60°C) for 15?min. They remain viable at ambient or reduced temperatures for days and may survive for weeks in sewage, dried foodstuffs, pharmaceutical agents, and fecal material. Like other members of the Enterobacteriaceae, *Salmonella* possesses somatic O antigens and flagellar H antigens. The **O antigens** are the heat-stable lipopolysaccharide components of the outer membrane; the **H antigens** are heat-labile proteins that can be present in phase 1 or 2. The Kauffmann-White scheme commonly used to classify salmonellae serotypes is based on O and H antigens. Serotyping is important clinically because

certain serotypes tend to be associated with specific clinical syndromes and because detection of an unusual serotype is sometimes useful in recognizing a common-source outbreak. A virulence capsular polysaccharide (Vi), present on *S.* ser. Typhi, is also found on strains of *S.* ser. Dublin and *S.* ser. Paratyphi C *(S.* ser. Hirschfeldii).

Epidemiology.

About 35,000–45,000 cases of culture-proven salmonellosis, approximately 98% of which are caused by nontyphoidal salmonellae, are reported annually in the United States. Because culturing and reporting are incomplete, the actual number of cases has been estimated as 1–5 million/yr. These figures are higher than those of the 1970s and may be related to modern practices of mass food production, which increase the potential for epidemic salmonellosis. About half of reported cases occur in persons <20 yr of age, and one third occur in children =4 yr of age; the highest isolation rate is for infants in the first few months of life. The age specific attack rate peaks in the second month of life in the United States at 159 cases/100,000 persons per year; in contrast, the incidence for persons 20–74 yr of age is about 9 cases/100,000 persons per year. Nontyphoidal *Salmonella* infections have a worldwide distribution, with an

TABLE 181.1-1 -- ***Salmonella* Nomenclature**

Traditional Usage	Formal Name	CDC Designation

**Some authorities prefer choleraesuis or enteritidis rather than enterica to describe the species.*

incidence related to water potability, sewage disposal, and food preparation practices.

In the United States, *Salmonella* infections occur with highest frequency in the warmer months, July through November. Although most reported cases of nontyphoidal salmonellosis occur sporadically, food-borne outbreaks are common. Each year, about 500 food-borne *Salmonella* outbreaks are reported, representing more than 50% of all gastroenteritis outbreaks with a documented bacterial cause. Some of the *Salmonella* outbreaks are widespread—interstate or even international—and affect thousands of individuals. Refinement of outbreak tracing has improved with the development of molecular epidemiology techniques, such as plasmid analysis and endonuclease digestion of chromosomal genes for recognition of small differences in chromosomal structure. These can “fingerprint” a particular clone and are especially useful in tracing outbreaks caused by common serotypes. The *Salmonella* serotypes most often encountered in the United States include *S.* ser. Typhimurium, *S.* ser. Enteritidis, *S.* ser. Heidelberg, and *S.* ser. Newport.

Animals constitute the principal source of human nontyphoidal *Salmonella* disease. Infected animals are often asymptomatic. *Salmonella* has been isolated from many animals, including poultry (i.e., chickens, turkeys, ducks), sheep, cows, pigs, birds, and domestic pets. Specific serotypes are associated with particular animal hosts. For example, children with *S.* ser. Marina typically have exposure to pet iguanas. Pets, especially reptiles, cause about 3% of the outbreaks. Animal-to-animal transmission may occur. Animal feeds containing fishmeal or bone meal contaminated with *Salmonella* are an important source of infection for animals. Moreover, subtherapeutic concentrations of antibiotics are often added to animal feed. Such practices promote the emergence of antibiotic-resistant bacteria, including *Salmonella*, in the gut flora of the animals. During slaughtering, these gut organisms may contaminate the meat, which is subsequently consumed by humans. Data suggest that animal antibiotic exposure may be responsible for antibiotic-resistant *Salmonella* infections in humans.

Poultry and poultry products (mainly eggs) cause about half of the common-source outbreaks. Foods containing raw or undercooked eggs (e.g., Caesar salad, egg-dipped bread, and homemade eggnog) are of special importance. *Salmonella* infections in chickens increase the risk for contamination of eggs. Salmonellae can contaminate the shell surface, penetrate the egg, or be transmitted from an ovarian infection directly to the egg yolk. *Salmonella* serotypes have been isolated in as many as 50% of poultry, 16% of pork, 5% of beef, and 40% of frozen egg products purchased in retail stores. Meats, especially beef and pork, cause about 13% of the

outbreaks, and raw or powdered milk and dairy products are the source of about 5% of the outbreaks. Food product–related outbreaks are often caused by contaminated equipment in processing plants or infected food handlers.

The estimated number of bacteria that must be ingested to cause symptomatic disease in healthy adults is 10^6 –10^8 *Salmonella* organisms. In infants and in persons with certain underlying conditions, the inoculum size that can produce disease is smaller. Because of the relatively high inoculum size of *Salmonella* infection, ingestion of contaminated food, in which the organisms can multiply, is a major source of human infection. Because of the high infecting dose, person-to-person transmission by direct fecal-oral spread is unusual but can occur, especially in young children. Perinatal transmission during vaginal delivery has been reported. Prior antibiotic therapy during the previous month increases risk of symptomatic infection in children.

Nosocomial infections have been related to contaminated medical instruments (particularly endoscopes) and diagnostic or pharmacologic preparations, particularly those of animal origin (e.g., pancreatic extracts, pituitary extracts, bile salts, pepsin, gelatin, vitamins, carmine dye). Food-borne nosocomial transmission is also possible. Hospitalized patients are at increased risk of severe and complicated *Salmonella* infections. Intravenous transmission by platelet transfusion has been reported.

After infection, nontyphoidal salmonellae are excreted in feces for a median of 5 wk. In young children and in individuals with symptomatic infections, the excretion period is longer. Prolonged carriage of *Salmonella* organisms is rare in healthy children but has been reported in those with underlying immune deficiency. During the period of *Salmonella* excretion, the individual may infect others, directly by the fecal-oral route or indirectly by contaminating foods.

Pathogenesis.

Enterocolitis is the typical disorder caused by nontyphoidal *Salmonella* infection. Findings include diffuse mucosal inflammation and edema, sometimes with erosions and microabscesses. Although *Salmonella* organisms are capable of penetrating the intestinal mucosa, neither destruction of epithelial cells nor production of ulcers is usually found. Intestinal inflammation, with polymorphonuclear leukocytes and macrophages, usually involves the lamina propria. Underlying intestinal lymphoid tissue and mesenteric lymph nodes enlarge and may develop small areas of necrosis. Such lymphoid hypertrophy may cause interference with the blood supply to the gut mucosa. Hyperplasia of the reticuloendothelial system is also noted within the liver and spleen. If bacteremia develops, it may lead to localized infection and suppuration in almost any organ.

The development of disease after infection with *Salmonella* depends on the number of infecting organisms, on their virulence traits, and on several host defense factors. Ingested *Salmonella* organisms reach the stomach, where acid is the first protective barrier. The acidity inhibits multiplication of the salmonellae, and most organisms are rapidly killed at gastric pH =2.0. Achlorhydria, buffering medications, rapid gastric emptying after gastrectomy or gastroenterostomy, and a large inoculum enable viable organisms to reach the small intestine. Neonates and young infants have hypochlorhydria and rapid gastric emptying, which contribute to their increased vulnerability to symptomatic salmonellosis. Because the transit time through the stomach is faster for drinks than for foods, a lower inoculum may cause disease in water-borne infection.

In the small and large intestines, salmonellae have to compete with normal bacterial flora to multiply and cause disease; prior antibiotic therapy disrupts this competitive relationship. Decreased intestinal motility due to anatomic causes or medications increases the contact time of the ingested salmonellae with the mucosa and the likelihood of symptomatic disease. After multiplication within the lumen, the organisms penetrate through the Peyer patches, typically at the distal part of the ileum and the proximal part of the colon. The penetration process includes specific attachment to the M cells, internalization by receptor-mediated endocytosis, cytoplasmic translocation of the infected

endosome to the basal membrane, and release of the salmonellae in the lamina propria. Dendritic cells in the dome of Peyer patches and beneath the gut epithelium begin the processing that leads to stimulation of CD4 T cells, interferon-? production, and bacterial clearance. Penetration usually occurs without destroying epithelial cells, and ulcers are not produced.

Heat-labile cholera-like enterotoxin is produced by many *Salmonella* isolates. This toxin and the prostaglandins that are produced locally increase cyclic adenosine monophosphate levels within intestinal crypts, causing a net efflux of electrolytes and water into the intestinal lumen.

Genes code for adherence, invasion, a cholera toxin-like enterotoxin, spread beyond the Peyer patches to mesenteric lymph nodes, intracellular growth in the liver and spleen, survival in macrophages, serum resistance, and complement resistance. The genes causing invasion are closely related to the *Shigella* invasion genes. However, *Shigella* lack the genes for spread beyond the intestine and survival in the bloodstream. These genetic differences explain the higher frequency of bacteremia in *Salmonella* infection. Some virulence traits are shared by all salmonellae, but others are serotype restricted. These virulence traits have been defined in tissue culture and murine models; it is likely that clinical features of human *Salmonella* infection will eventually be related to specific DNA sequences.

With most diarrhea-associated nontyphoidal salmonelloses, the infection does not extend beyond the lamina propria and the local lymphatics. *S. ser*. Dublin and *S. ser*. Choleraesuis rapidly invade the bloodstream with little or no intestinal involvement. Specific virulence genes are related to the ability to cause bacteremia. These genes are found significantly more often in strains of *S*. ser. Typhimurium isolated from the blood than the feces of humans. Bacteremia, however, is possible with any *Salmonella* serotype, especially in individuals with reduced host defenses. An impaired reticuloendothelial or cellular immune response is important. Children with chronic granulomatous disease, other white cell disorders, and AIDS are at increased risk. A central role for IL-12 and interferon-? cell-mediated immunity in clearance of *Salmonella* has been demonstrated by inherited defects in this pathway. These defects (interferon-? receptor binding chain or signaling chain deficiency,

IL-12 receptor beta 1 chain deficiency, IL-12 p40 subunit deletion) cause decreased interferon-? production. These genetic defects are associated with both *Salmonella* and mycobacterial infections.

Children with sickle cell disease are prone to *Salmonella* septicemia and osteomyelitis. The numerous infarcted areas in the gastrointestinal tract, bones, and reticuloendothelial system may initially permit organisms greater access to the circulation from the intestine and then furnish an optimal environment for localization. The decreased phagocytic and opsonizing capacity of patients with sickle cell disease also contributes to the high infection rate.

Chronic infection is associated with cholelithiasis, *Schistosoma mansoni* infection with hepatosplenic involvement, and *Schistosoma hematobium* infection of the urinary tract. Localized infections are more common in areas with impaired local defenses (e.g., effusions, tumors, hematomas).

Clinical Manifestations.

Several distinct clinical syndromes can develop in children infected with nontyphoidal *Salmonella*, depending on host factors and the specific serotype involved.

ACUTE ENTERITIS.

The most common clinical presentation of salmonellosis is acute enteritis. After an incubation period of 6–72?hr (mean, 24?hr), there is an abrupt onset of nausea, vomiting, and crampy abdominal pain primarily in the periumbilical area and right lower quadrant, followed by mild to severe watery diarrhea and sometimes by diarrhea containing blood and mucus. Moderate fever (temperature of 101–102℉ [38.5–39℃]) affects about 70% of patients. Some children develop severe disease with high fever, headache, drowsiness, confusion, meningismus, seizures, and abdominal distention. Abdominal examination reveals some tenderness. The stool typically contains a moderate number of polymorphonuclear leukocytes and occult blood. Mild leukocytosis may be detected. Symptoms subside within 2–7 days in healthy children; fatalities are rare.

In certain high-risk groups, the course of *Salmonella* gastroenteritis may be more complicated. Neonates, young infants, and children with primary or secondary immune deficiency may have symptoms persisting for several weeks. In patients with AIDS, the infection may become widespread and overwhelming, causing multisystem involvement, septic shock, and death. In patients with inflammatory bowel disease, especially active ulcerative colitis, *Salmonella* gastroenteritis may cause invasion of the bowel with rapid development of toxic megacolon, systemic toxicity, and death. Patients with schistosomiasis have increased susceptibility to salmonellosis and exhibit persistence of infection unless the schistosomiasis is also treated. *Salmonella* organisms are able to multiply within the schistosomes, where they are protected from antibiotics.

BACTEREMIA.

In contrast to adults who usually are immunologically impaired and develop *Salmonella* bacteremia in the absence of diarrhea, the majority of children have no predisposing risk factors and develop bacteremia as a complication of acute enteritis. The older a child is, the more likely he is to have an underlying condition when *Salmonella* bacteremia occurs. Transient bacteremia during nontyphoidal *Salmonella* gastroenteritis is believed to occur in 1–5% of patients. The precise incidence is unclear, because blood cultures often are not obtained from patients with *Salmonella* gastroenteritis, especially those who are not hospitalized, and because most data are from retrospective studies. *Salmonella* bacteremia is associated with fever, chills, and often with a toxic appearance. Bacteremia has been documented, however, in afebrile, well-appearing children, including neonates. Prolonged or intermittent bacteremia is associated with low-grade fever, anorexia, weight loss, diaphoresis, and myalgias. Children with certain underlying conditions and *Salmonella* gastroenteritis are at increased risk of bacteremia (Box 181–1), which may lead to extraintestinal infection. Children who have no underlying disease may be at increased risk of bacteremia if they have been treated with antibiotics in the month before acquisition of *Salmonella* infection. Bacteremic disease after antibiotic treatment is more likely to be due to a resistant *Salmonella*. In patients with AIDS, recurrent septicemia appears despite antibiotic therapy, often with a negative stool culture for *Salmonella* and sometimes with no identifiable focus of infection. In children, persistent bacteremia usually occurs without an intravascular focal infection, although adults with persistent bacteremia may have endocarditis, arteritis, or an infected aortic aneurysm. Prolonged or recurrent bacteremia also occurs in patients with schistosomiasis. Hemolytic anemias, malaria, and bartonellosis are associated with an increased risk

Box 181.1-1. Conditions That Increase the Risk of *Salmonella* Bacteremia During *Salmonella* Gastroenteritis

- Neonates and young infants (=3 mo of age)
- AIDS, chronic granulomatous disease, and other immuno deficiencies
- Malignancies, especially leukemia and lymphoma
- Immunosuppressive and corticosteroid therapy
- Hemolytic anemia, including sickle cell disease, malaria, and bartonellosis
- Collagen vascular disease
- Inflammatory bowel disease
- Gastrectomy or gastroenterostomy
- Achlorhydria or antacid medication

- Inflammatory bowel disease
- Gastrectomy or gastroenterostomy
- Achlorhydria or antacid medication use
- Impaired intestinal motility
- Schistosomiasis
- Malnutrition

of bacteremia, presumably because of reticuloendothelial system dysfunction. In pregnancy, *Salmonella* septicemia and fetal loss have been reported. *S.* ser. Typhimurium is the most common serotype causing *Salmonella* bacteremia in the United States.

EXTRAINTESTINAL FOCAL INFECTIONS.

After salmonellae have entered the bloodstream, they have a unique capability to metastasize and cause a focal suppurative infection of almost any organ. Sites of pre-existing abnormalities are often involved. Extraintestinal infections are most common in the first 3 mo of life, in those with sickle cell disease, and in those who have had prior gastrointestinal surgery. The most common focal infections involve the skeletal system, meninges, and intravascular sites. *Salmonella* is a common cause of osteomyelitis in children with sickle cell disease. *Salmonella* osteomyelitis and suppurative arthritis also occur in sites of previous trauma or skeletal prosthesis. Reactive arthritis may follow *Salmonella* gastroenteritis, usually in adolescents with the HLA-B27 antigen. Meningitis occurs about 100 times less frequently than bacteremia. Although meningitis can occur at any age, the peak incidence is in infancy. Patients may present with little or no fever and minimal symptoms, or rapid deterioration, and neurologic sequelae despite appropriate antibiotic therapy. *Salmonella* meningitis occurs also in patients with AIDS, for whom the mortality rate is more than 50%, and relapse and brain abscesses can occur.

Diagnosis.

Definitive diagnosis of the various clinical syndromes is still based on culturing and subsequent identification of *Salmonella* organisms. In children with gastroenteritis, cultures of stools have higher yields than rectal swabs. In patients with sites of local suppuration, aspirated specimens should be Gram stained and cultured. *Salmonella* organisms grow well on nonselective or enriched media, such as blood agar, chocolate agar, or nutrient broth. Normally sterile body fluids (e.g., cerebrospinal fluid, joint fluid, urine) can be cultured on any of these. For specimens normally containing mixed bacterial flora (e.g., stools), selective media, such as MacConkey, XLD, bismuth sulfite (BBL), or *Salmonella-Shigella* (SS) agar, which inhibit the growth of normal flora, should be used.

Several methods are being developed to answer the need for rapid diagnosis. Tests based on latex agglutination and fluorescence are commercially available for the rapid diagnosis of *Salmonella* colonies growing in stool culture enrichment broth or culture plates. Serologic assay for detecting antibodies against *S.* ser. Typhimurium and *S.* ser. Enteritidis has been reported, but clinical usefulness is unclear. The serotype isolated can suggest a source that may be epidemiologically important: *S.* ser. Kentucky and *S.* ser. Heidelberg in broilers; *S.* ser Hadar and *S.* ser. Heidelberg in turkeys; *S.* ser. Derby and *S.* ser. Typhimurium in swine; and *S.* ser. Marina, *S.* ser. Flint, *S.* ser. Kintambo, *S.* ser. Wassenaar, *S.* ser. Ealing, *S.* ser. Carrau, *S.* ser. Stanley, *S.* ser. Java, and *S.* ser. Abaetetuba in reptiles.

DIFFERENTIAL DIAGNOSIS.

Salmonella gastroenteritis should be differentiated from other bacterial, viral, and parasitic causes of diarrhea. The presentation of inflammatory diarrhea with moderate fever should be particularly differentiated from *Shigella*, enteroinvasive *Escherichia coli, Yersinia enterocolitica*, and *Clostridium difficile* infections. Rotavirus infections in infants can mimic *Salmonella* enterocolitis. Etiologic diagnosis on the basis of the clinical picture is seldom possible. Epidemiologic data may be helpful. If abdominal pain and tenderness are severe, appendicitis, perforated viscus, and ulcerative colitis merit consideration in the differential diagnosis.

Treatment.

Appropriate therapy depends on the specific clinical presentation of *Salmonella* infection. Assessment of the hydration status, correction of dehydration and electrolyte disturbances, and supportive care (Chapters 46 and 48.1) are the most important aspects of managing *Salmonella* gastroenteritis in children. Antimotility agents prolong intestinal transit time and are thought to increase the risk of invasion; they should not be used when salmonellosis is suspected. In patients with gastroenteritis, antimicrobial agents do not shorten the clinical course, nor do they eliminate fecal excretion of *Salmonella*. By suppressing normal intestinal flora, antimicrobial agents may prolong the excretion of *Salmonella* and increase the risk of creating the chronic carrier state. Antibiotics therefore are not indicated routinely in treating *Salmonella* gastroenteritis. They should be used in infants (=3 mo of age) and other children who are at increased risk of a disseminated disease (see Box 181–1) and in those with a severe or protracted course. It has been recommended that toxic megacolon should be managed with adequate hydration and insertion of a rectal tube to decompress the dilated colon in an attempt to prevent perforation.

Children with bacteremia or extraintestinal focal *Salmonella* infections should receive antimicrobial therapy. Ampicillin (200?mg/kg/24?hr divided qid) is efficacious and used to be the drug of choice; trimethoprim-sulfamethoxazole (TMP-SMZ; 10?mg/kg/24?hr of the TMP component and 50?mg/kg/24?hr of the SMZ divided bid) is also effective. Because of the increasing worldwide antibiotic resistance of *Salmonella* strains, it is necessary to perform susceptibility tests on all human isolates. About 20% of *Salmonella* isolates in the United States are resistant to ampicillin. Multiresistance to ampicillin, TMP-SMZ, and chloramphenicol has been reported. The third-generation cephalosporins cefotaxime (150–200?mg/kg/24?hr divided q 6–8?hr) or ceftriaxone (100?mg/kg/24?hr in one or two daily doses) are effective if the isolate is susceptible. Ceftriaxone resistant salmonellae are being recognized with increasing frequency in the United States among individuals who have not traveled internationally. Their prevalence has increased from 0.1% in 1996

to 0.5% in 1998. Ceftriaxone resistant organisms have been traced to cattle. Quinolones are also effective, but they are not approved for use in persons =18 yr of age because of the potential damage to growing cartilage. Rarely, use of a fluoroquinolone may be appropriate in a child whose organism is resistant to other first-line choices. Unfortunately, *S.* ser. Typhimurium DT104, an organism that has spread from food animals to humans and has caused large outbreaks, is multidrug resistant, sometimes including resistance to quinolones. In children with severe disease, initial treatment with a third-generation cephalosporin is recommended until antibiotic susceptibility is known. Thereafter, antibiotics should be changed on the basis of susceptibility data and clinical syndrome.

The duration of antimicrobial therapy is 10–14 days for children with bacteremia, 4–6 wk for acute osteomyelitis, and 4 wk for meningitis. For children with a focal suppurative process, surgical drainage is necessary in addition to antibiotic treatment. Surgical intervention is often necessary in intravascular *Salmonella* infections and in cases of chronic osteomyelitis.

Prognosis.

Complete recovery is the rule in healthy children who develop *Salmonella* gastroenteritis. Young infants and immunocompromised patients often have systemic involvement, a prolonged course, and extraintestinal foci. The prognosis is poor for children with *Salmonella* meningitis or endocarditis.

CHRONIC CARRIER STATE.

After clinical recovery from *Salmonella* gastroenteritis, asymptomatic fecal excretion of salmonellae occurs for several months, particularly in younger children or those treated with antibiotics. A chronic carrier state is defined as asymptomatic excretion of *Salmonella* organisms for >1 yr. A prolonged carrier state after nontyphoidal salmonellosis is rare (<1%); it is more common in patients with biliary tract disease (e.g., cholelithiasis). The only significance of asymptomatic fecal excretion of nontyphoidal *Salmonella* is the potential transmission of the infection to other individuals.

Prevention.

Chlorinated water, proper sanitary systems, and adequate food hygiene practices are necessary to prevent nontyphoidal salmonellosis in humans. Handwashing is of paramount

importance in controlling person-to-person transmission by means of food. In hospitalized patients, enteric precautions should be used for the duration of illness. Individuals with symptomatic or asymptomatic excretion of *Salmonella* strains should be excluded from activities that involve food preparation or child care until repeated stool cultures are negative. Breast-feeding has been shown to reduce infection.

Control of the transmission of *Salmonella* infections to humans requires control of the infection in the animal reservoir, judicious use of antibiotics in dairy and livestock farming, prevention of contamination of foodstuffs prepared from animals, and use of appropriate standards in food processing in commercial and private kitchens. Parents should be advised of the risk of reptiles as pets in households with young infants. Whenever cooking practices prevent food from reaching a temperature greater than 150°F (65.5°C) for >12?min, *Salmonella* may remain viable. Because large outbreaks are often related to mass food production, it should be recognized that contamination of just one piece of machinery used in food processing may cause an outbreak; meticulous cleaning of equipment is essential. No vaccine against nontyphoidal *Salmonella* infections is available. Infections should be reported to public health authorities so that outbreaks can be recognized and investigated.

181.2 Enteric Fever

Etiology.

Enteric fever, or **typhoid fever**, is caused by *S.* ser Typhi, *S.* ser. Paratyphi A, *S.* ser. Paratyphi B (Schottmuelleri), and *S.* ser. Paratyphi C (Hirschfeldii). Rarely, other *Salmonella* serotypes can cause a similar prolonged febrile illness.

Epidemiology.

The incidence, mode of transmission, and consequences of enteric fever differ significantly in developed and developing countries. The incidence has decreased markedly in developed countries. In the United States, about 400 cases of typhoid fever are reported each year, giving an annual incidence of less than 0.2 cases/100,000 population, which is similar to that in Western Europe and Japan. In Southern Europe, the annual incidence is 4.3–14.5 cases/100,000 population. In developing countries, *S.* ser. Typhi is often the most common *Salmonella* isolate, with an incidence that can reach 500 cases/ 100,000 population (0.5%) and a high mortality rate. The World Health Organization has estimated that at least 12.5 million cases occur annually worldwide.

Because humans are the only natural reservoir of *S.* ser. Typhi, direct or indirect contact with an infected person (sick or chronic carrier) is necessary for infection. Ingestion of foods or water contaminated with human feces is the most common mode of transmission. Water-borne outbreaks due to poor sanitation and direct fecal-oral spread due to poor personal hygiene are encountered, mainly in developing countries. Oysters and other shellfish cultivated in water contaminated by sewage are also a source of widespread infection. In the United States about 65% of the cases result from international travel. Travel to Asia (especially to India) and Central or South America (especially Mexico) is usually implicated. Domestically acquired enteric fever is most frequent in the southern and western United States and is usually caused by consumption of foods contaminated by individuals who are chronic carriers. Congenital transmission of enteric fever can occur by transplacental infection from a bacteremic mother to her fetus. Intrapartum transmission is also possible, occurring by a fecal-oral route from a carrier mother.

Pathogenesis.

In younger children, the morphologic changes of *S.* ser. Typhi infection are less prominent than in older children and adults. Hyperplasia of Peyer patches with necrosis and sloughing of overlying epithelium produces ulcers that may bleed. The mucosa and lymphatic tissue of the intestinal tract are severely inflamed and necrotic. Ulcers heal without scarring. Strictures and intestinal obstruction virtually never occur after typhoid fever. The inflammatory lesion may occasionally penetrate the muscularis and serosa of the intestine and produce perforation. The mesenteric lymph nodes, liver, and spleen are hyperemic and generally reveal areas of focal necrosis. Hyperplasia of reticuloendothelial tissue with proliferation of mononuclear cells is the predominant finding. A mononuclear response may be seen in the bone marrow in association with areas of focal necrosis. Inflammation of the gallbladder is focal, inconstant, and modest in proportion to the extent of local bacterial multiplication. Bronchitis is common. Inflammation also may be observed in the form of localized abscesses, pneumonia, septic arthritis, osteomyelitis, pyelonephritis, endophthalmitis, and meningitis.

The inoculum size required to cause enteric fever in volunteers is 10^5 –10^9 *S.* ser. Typhi organisms. These estimates may be higher than in naturally acquired infection because the volunteers ingested the organisms in milk; stomach acidity is an important determinant of susceptibility to *Salmonella*. The bacteria invade through the Peyer patches. Organisms are transported to intestinal lymph nodes, where multiplication takes place within the mononuclear cells. Monocytes, unable to destroy the bacilli early in the disease process, carry these organisms into the mesenteric lymph nodes. Organisms then reach the bloodstream through the thoracic duct, causing a transient bacteremia. Circulating organisms reach the reticuloendothelial cells in the liver, spleen, and bone marrow and may seed other organs. After proliferation in the reticuloendothelial system, bacteremia recurs. The gallbladder is particularly susceptible to being infected. Local multiplication in the walls of the gallbladder produces large numbers of salmonellae, which reach the intestine through the bile.

Several virulence factors seem to be important. Invasion of Peyer patches is encoded by genes closely related to the invasion genes of *Shigella* and enteroinvasive *E. coli*. However, *S.* ser. Typhi possesses a number of additional genes not found in *Shigella* that are responsible for the features of typhoid fever. The surface Vi capsular antigen found in *S.* ser. Typhi interferes with phagocytosis by preventing the binding of C3 to the surface of the bacterium. The ability of organisms to survive within macrophages after phagocytosis is an important virulence trait encoded by the *phoP* regulon; it may be related to metabolic effects on host cells. Circulating endotoxin, a lipopolysaccharide component of the bacterial cell wall, is thought to cause the prolonged fever and toxic symptoms of enteric fever, although its levels in symptomatic patients are low. Alternatively, endotoxin-induced cytokine production by human macrophages may cause the systemic symptoms. The occasional occurrence of diarrhea may be explained by presence of a toxin related to cholera toxin and *E. coli* heat-labile enterotoxin.

Cell-mediated immunity is important in protecting the human host against typhoid fever. Decreased numbers of T lymphocytes are found in patients who are critically ill with typhoid fever. Carriers show impaired cellular reactivity to *S.* ser. Typhi antigens in the leukocyte migration inhibition test. In carriers, a large number of virulent bacilli pass into the intestine daily and are excreted in the stool, without entering the epithelium of the host.

Clinical Manifestations.

The incubation period is usually 7–14 days, but it may range from 3–30 days, depending mainly on the size of the ingested inoculum. The clinical manifestations of enteric fever depend on age.

SCHOOL-AGED CHILDREN AND ADOLESCENTS.

The onset of symptoms is insidious. Initial symptoms of fever, malaise, anorexia, myalgia, headache, and abdominal pain develop over 2–3 days. Although diarrhea having a pea soup consistency may be present during the early course of the disease, constipation later becomes a more prominent symptom. Cough and epistaxis may ensue. Severe lethargy may develop in some children.

Temperature, which increases in a stepwise fashion, becomes an unremitting and high fever within 1 wk, often reaching 40°C.

During the 2nd week of illness, high fever is sustained, and fatigue, anorexia, cough, and abdominal symptoms increase in severity. Patients appear acutely ill, disoriented, and lethargic. Delirium and stupor may be observed. Physical findings include a relative bradycardia, which is disproportionate to the high fever. Hepatomegaly, splenomegaly, and distended abdomen with diffuse tenderness are very common. In about 50% of patients with enteric fever, a macular or maculopapular rash (**rose spots**) appears on about the 7th–10th day. Lesions are usually discrete, erythematous, and 1–5?mm in diameter; the lesions are slightly raised and blanch on pressure. They appear in crops of 10–15 lesions on the lower chest and abdomen and last 2–3 days. They leave a slight brownish discoloration of the skin on healing. Cultures of the lesions have a 60% yield for *Salmonella* organisms. Rhonchi and scattered rales may be heard on auscultation of the chest. Nausea and vomiting if occurring in the 2nd or 3rd week suggest a complication. If no complications occur, the symptoms and physical findings gradually resolve within 2–4 wk, but malaise and lethargy may persist for an additional 1–2 mo. Patients may be emaciated by the end of the illness. Enteric fever caused by nontyphoidal *Salmonella* is usually milder, with a shorter duration of fever and a lower rate of complications.

INFANTS AND YOUNG CHILDREN (<5?YR).

Enteric fever is relatively rare in this age group in endemic areas. Although clinical sepsis can occur, the disease is surprisingly mild at presentation, making the diagnosis difficult. Mild fever and malaise, misinterpreted as a viral syndrome, occur in infants with culture-proven typhoid fever. Diarrhea is more common in young children with typhoid fever than in adults, leading to a diagnosis of acute

gastroenteritis.

NEONATES.

In addition to its ability to cause abortion and premature delivery, enteric fever during late pregnancy may be transmitted vertically. The neonatal disease usually begins within 3 days of delivery. Vomiting, diarrhea, and abdominal distention are common. Temperature is variable but may be as high as 40.5°C. Seizures may occur. Hepatomegaly, jaundice, anorexia, and weight loss can be marked.

Complications.

Severe intestinal hemorrhage and intestinal perforation occur in 1–10% and 0.5–3% of the patients, respectively. These and most other complications usually occur after the 1st week of the disease. Hemorrhage, which usually precedes perforation, is manifested by a decrease in temperature and blood pressure and an increase in the pulse rate. Perforations, which are usually pinpoint size but may be as large as several centimeters, typically occur in the distal ileum and are accompanied by a marked increase in abdominal pain, tenderness, vomiting, and signs of peritonitis. Sepsis with various enteric aerobic gram-negative bacilli and anaerobes may develop. Although disturbed liver function test results are found for many patients with enteric fever, overt hepatitis and cholecystitis are considered complications. An increase in serum amylase levels may sometimes accompany clinically obvious pancreatitis.

Pneumonia caused by superinfection with organisms other than *Salmonella* is more common in children than in adults. In children, pneumonia or bronchitis is common (approximately 10%). Toxic myocarditis with fatty infiltration and necrosis of the myocardium may be manifested by arrhythmias, sinoatrial block, ST-T changes on the electrocardiogram, or cardiogenic shock. Thrombosis and phlebitis occur rarely. Neurologic complications include increased intracranial pressure, cerebral thrombosis, acute cerebellar ataxia, chorea, aphasia, deafness, psychosis, and transverse myelitis. Peripheral and optic neuritis have been reported. Permanent sequelae are rare. Other reported complications include fatal bone marrow necrosis, pyelonephritis, nephrotic syndrome, meningitis, endocarditis, parotitis, orchitis, and suppurative lymphadenitis. Although osteomyelitis and suppurative arthritis can occur in a normal host, they are more common in children with hemoglobinopathies.

Diagnosis.

Culturing the *Salmonella* strain involved is usually the basis for confirming the diagnosis. Results of blood cultures are positive in 40–60% of the patients seen early in the course of the disease, and stool and urine cultures become positive after the 1st week. The stool culture result is also occasionally positive during the incubation period. Because of the intermittent and low-level bacteremia, repeated blood cultures should be obtained in suspect cases. Cultures of bone marrow often yield positive results during later stages of the disease, when blood cultures may be sterile; although seldom obtained, cultures of mesenteric lymph nodes, liver, and spleen may also have positive results at this point. A culture of bone marrow is the single most sensitive method of diagnosis (positive in 85–90%) and is less influenced by prior antimicrobial therapy. Stool and sometimes urine cultures are positive in chronic carriers. In suspected cases with negative results of stool cultures, a culture of aspirated duodenal fluid or of a duodenal string capsule may be helpful in confirming infection. However, the duodenal string culture test cannot be performed on those too young or too ill to cooperate.

Direct detection of *S*. ser. Typhi-specific antigens in the serum or *S*. ser. Typhi Vi antigen in the urine has been attempted by immunologic methods, often using monoclonal antibodies. Polymerase chain reaction has been used to amplify specific genes of *S*. ser. Typhi in the blood of patients, enabling diagnosis within a few hours. This method is specific and more sensitive than blood cultures, given the low level of bacteremia in enteric fever. Serology is of little help in establishing the diagnosis, but it may be useful in epidemiologic studies. The classic **Widal test** measures antibodies against O and H antigens of *S*. ser. Typhi. Because many false-positive and false-negative results occur, diagnosis of typhoid fever by Widal test alone is prone to error.

A normochromic, normocytic anemia often develops after several weeks of illness and is related to intestinal blood loss or bone marrow suppression. Blood leukocyte counts are frequently low in relation to the fever and toxicity, but there is a wide range in counts; leukopenia, usually not less than 2,500 cells/mm^3 , is often found after the 1st or 2nd week of illness. When pyogenic abscesses develop, leukocytosis may reach 20,000–25,000/mm^3 . Thrombocytopenia may be striking and persist for as long as 1 wk. Liver function test results are often disturbed. Proteinuria is common. Fecal leukocytes and fecal blood are very common.

DIFFERENTIAL DIAGNOSIS.

During the initial stage of enteric fever, the clinical diagnosis may mistakenly be gastroenteritis, viral syndrome, bronchitis, or bronchopneumonia. Subsequently, the differential diagnosis includes sepsis with other bacterial pathogens; infections caused by intracellular microorganisms, such as tuberculosis, brucellosis, tularemia, leptospirosis, and rickettsial diseases; viral infections, such as infectious mononucleosis and anicteric hepatitis; and malignancies, such as leukemia and lymphoma.

Treatment.

Antimicrobial therapy is essential in treating enteric fever. Because of increasing antibiotic resistance, however, choosing the appropriate empirical therapy is problematic and controversial. Although antibiotic resistance of *S*. ser. Typhi isolates in the United States is relatively low (3–4%), most infections are acquired abroad, where resistance occurs. Increasing rates of plasmid-mediated antibiotic resistance of *S*. ser. Typhi have been reported from Southeast Asia, Mexico, and certain countries in the Middle East. Reports from India describe multiresistance to chloramphenicol, ampicillin, and TMP-SMX in 49–83% of *S*. ser. Typhi isolates. Resistant strains are usually susceptible to third-generation cephalosporins. Quinolones are

efficacious but are not approved for children. Most antibiotic regimens are associated with a 5–20% recurrence risk. Chloramphenicol (50?mg/kg/24?hr divided qid PO or 75?mg/kg/24?hr divided q 6?hr IV), ampicillin (200?mg/kg/24?hr divided q 4–6?hr IV), amoxicillin (100?mg/kg/24?hr divided tid PO), and trimethoprim-sulfamethoxazole (10?mg of TMP and 50?mg of SMZ/kg/24?hr divided bid PO) have demonstrated good clinical efficacy. Although chloramphenicol therapy is associated with a more rapid defervescence and sterilization of blood, the rate of relapse is somewhat higher, and this agent can cause potentially serious adverse effects. Most children become afebrile within 7 days; treatment of uncomplicated cases should be continued for at least 14 days, or 5–7 days after defervescence. Data suggest that very short courses of therapy may be adequate with oral cefixime (20?mg/kg/24?hr divided bid for 7 days), ceftriaxone (50?mg/kg/24?hr once daily IM for 5 days) or oral ofloxacin (15?mg/kg/24?hr for 2 days). Chloramphenicol remains the gold standard.

In adults, ciprofloxacin at a dose of 500?mg bid for 7–10 days is effective and associated with a low relapse rate. In children with suspected resistant strains, empirical therapy with ceftriaxone (or cefotaxime) is appropriate until antibiotic susceptibility patterns are available.

In addition to antibiotic therapy, a short course of dexamethasone (3?mg/kg for the initial dose, followed by 1?mg/kg q 6?hr for 48?hr) improves the survival rate of patients with shock, obtundation, stupor, or coma. Supportive treatment and maintenance of appropriate fluid and electrolyte balance are essential. When intestinal hemorrhage is severe, blood transfusion is needed. Surgical intervention and broad-spectrum antibiotics are recommended for intestinal perforation. Surgical resection of 10?cm on each side of the perforation has been reported to improve survival. Platelet transfusions have been suggested for the treatment of thrombocytopenia that is sufficiently severe to cause intestinal hemorrhage in patients for whom surgery is contemplated.

Although attempts to eradicate chronic carriage of *S.* ser. Typhi are recommended for public health considerations, eradication is difficult despite in vitro susceptibility to the usual antibiotics. A course of 4–6 wk of high-dose ampicillin (or amoxicillin) plus probenecid or TMP-SMZ results in an approximately 80% cure rate of carriers if no biliary tract disease is present. Ciprofloxacin has been used successfully in adults. In the presence of cholelithiasis or cholecystitis, antibiotics alone are unlikely to be successful; cholecystectomy within 14 days of antibiotic treatment is recommended.

Prognosis.

The prognosis for a patient with enteric fever depends on prompt therapy, the age of the patient, previous state of health, the causative *Salmonella* serotype, and the appearance of complications. In developed countries, with appropriate antimicrobial therapy, the mortality rate is less than 1%. In developing countries, the mortality rate is higher than 10%, usually because of delays in diagnosis, hospitalization, and treatment. Infants and children with underlying debilitating disorders are at higher risk. The appearance of complications, such as gastrointestinal perforation or severe hemorrhage, meningitis, endocarditis, and pneumonia, is associated with high morbidity and mortality rates.

Relapse after the initial clinical response occurs in 4–8% of the patients who are not treated with antibiotics. In patients who have received appropriate antimicrobial therapy, the clinical manifestations of relapse become apparent about 2 wk after stopping antibiotics and resemble the acute illness. The relapse, however, is usually milder and of shorter duration. Numerous relapses may occur. Individuals who excrete *S.* ser. Typhi for =3 mo after infection usually become chronic carriers. The risk of becoming a carrier is low in children and increases with age; of all patients with typhoid fever, 1–5% become chronic carriers. The incidence of biliary tract diseases is higher in chronic carriers than in the general population. Although chronic urinary carriage may also occur, it is rare and found mainly in individuals with schistosomiasis.

Prevention.

In endemic areas, improved sanitation and clean running water are essential to control enteric fever. To minimize person-to-person transmission and food contamination, personal hygiene measures, handwashing, and attention to food preparation practices are necessary. Efforts to eradicate *S.* ser. Typhi from carriers are recommended, because humans are the only reservoir of *S.* ser. Typhi. When such efforts are unsuccessful, carriers should be prevented from working in food- or water-processing activities, in kitchens, and in occupations related to patient care. These individuals should be made aware of the potential contagiousness of their condition and of the importance of handwashing and attentive personal hygiene.

VACCINE.

Two vaccines against *S.* ser. Typhi are commercially available in the United States. An oral, live-attenuated preparation of the Ty21a strain of *S.* ser. Typhi have been shown to have good efficacy (67–82%). Four enteric-coated capsules are given on alternate days, and the entire series is repeated every 5 yr. Significant adverse effects are rare. The oral vaccine is recommended for persons =6 yr of age. Infants and toddlers do not develop immune responses with this preparation. It should not be used in persons with immunodeficiency syndromes. The Vi capsular polysaccharide can be used in persons =2 yr of age. It is given as a single intramuscular dose, with a booster every 2 yr.

Typhoid vaccination is recommended to travelers to endemic areas, especially Latin America, Southeast Asia, and Africa. Such travelers need to be cautioned that the vaccine is not a substitute for personal hygiene and careful selection of foods and drinks, because none of the vaccines has efficacy approaching 100%. Vaccination is also recommended to individuals with intimate exposure to a documented carrier and for control of outbreaks.

Chapter 182 - *Shigella*

Thomas G. Cleary

Although dysenteric syndromes have long been recognized as a scourge of humans, it is only in the past century that the bacteriology of the most common form of epidemic dysentery, shigellosis, has been appreciated.

Etiology.

Four species of *Shigella* are responsible for shigellosis: *S. dysenteriae* (serogroup A), *S. flexneri* (serogroup B), *S. boydii* (serogroup C), and *S. sonnei* (serogroup D). There are 13 serotypes in group A, six serotypes and 15 subserotypes in group B, 18 serotypes in group C, and one serotype in group D.

Epidemiology.

Infection with shigellae occurs most often during the warm months in temperate climates and during the rainy season in tropical climates. Both sexes are affected equally. Although infection can occur at any age, it is most common in the 2nd and 3rd year of life. Infection in the first 6 mo of life is rare for reasons that are not clear. Breast milk, which in endemic areas contains antibodies to both virulence plasmid-coded antigens and lipopolysaccharides, may partially explain the age-related incidence. Asymptomatic infection of children and adults occurs commonly in endemic areas.

In industrialized societies, *S. sonnei* is the most common cause of bacillary dysentery, with *S. flexneri* second in frequency; in pre-industrial societies, *S. flexneri* is most common, with *S. sonnei* second in frequency. *S. dysenteriae* serotype 1 tends to occur in massive epidemics, although it is also endemic in Asia and Africa.

TRANSMISSION.

Contaminated food (often a salad or other item requiring extensive handling of the ingredients) and water are important vectors. However, person-to-person transmission is probably the major mechanism of infection in most areas of the world. Spread within families, custodial institutions, and child-care centers demonstrates the ability of low numbers of organisms to cause disease on a person-to-person basis.

Shigellae require very low inocula to cause illness. Ingestion of as few as 10 *S. dysenteriae* serotype 1 organisms can cause dysentery in some susceptible individuals. This is in contrast to organisms such as *Vibrio cholerae*, which require ingestion of 10^8 –10^{10} organisms to cause illness. The inoculum effect explains the ease of person-to-person transmission of shigellae in contrast to *V. cholerae*.

Pathogenesis.

The basic virulence trait shared by all shigellae is the ability to invade intestine. This characteristic is encoded on a large (120–140 megadalton) plasmid that is responsible for synthesis of a group of polypeptides involved in cell invasion and killing. Shigellae that lose the virulence plasmid are no longer pathogenic. *Escherichia coli* that harbor this plasmid (enteroinvasive *E. coli*) behave clinically like shigellae. In addition to the major plasmid-encoded virulence traits, chromosomally encoded factors are also required for full virulence; some of these chromosomal traits are important for all shigellae (e.g., lipopolysaccharide synthesis), whereas others are important in some serotypes (e.g., Shiga toxin synthesis by *S. dysenteriae* serotype 1 and ShET-1 by *S. flexneri* 2a). **Shiga toxin**, a potent protein synthesis-inhibiting exotoxin, is produced in significant amounts by *S. dysenteriae* serotype 1, by certain *E. coli*, which are known as Shiga toxin–producing *E. coli* (STEC), and rarely by other organisms. The watery diarrhea phase of shigellosis may be caused by enterotoxins.

The pathologic changes of shigellosis take place primarily in the colon, the target organ for shigellae. The changes are most intense in the distal colon, although pancolitis may occur. Grossly, localized or diffuse mucosal edema, ulcerations, friable mucosa, bleeding, and exudate may be seen. Microscopically, ulcerations, pseudomembranes, epithelial cell death, infiltration extending from the mucosa to the muscularis mucosae by polymorphonuclear and mononuclear cells, and submucosal edema occur.

IMMUNITY.

Secretory IgA and serum antibodies develop within days to weeks after infection with *Shigella*. Both antilipopolysaccharide and antivirulence plasmid polypeptide antibodies have been described; protection is serotype specific. Induction of multiple cytokines and brisk inflammatory responses is followed by healing. Interferon-? produced by NK cells is critically important to resistance.

Clinical Manifestations.

Bacillary dysentery is clinically similar regardless of whether the disease is caused by any of the four species of *Shigella* or an enteroinvasive *E. coli* (Chapter 183); however, there are some clinical differences, particularly relating to the greater severity and risk of complications with *S. dysenteriae* serotype 1 infection.

Ingestion of shigellae is followed by an incubation period of 12?hr to several days before symptoms ensue. Severe abdominal pain, high fever, emesis, anorexia,

generalized toxicity, urgency, and painful defecation characteristically occur. Physical examination at this point may show abdominal distention and tenderness, hyperactive bowel sounds, and a tender rectum on digital examination.

The diarrhea may be watery and of large volume initially, evolving into frequent small-volume, bloody mucoid stools; however, some children never progress to the stage of bloody diarrhea, whereas in others the first stools are bloody. Significant dehydration related to the fluid and electrolyte losses in both feces and emesis can occur. Untreated diarrhea may last 1–2 wk; only about 10% of patients have diarrhea persisting for more than 10 days. Persistent diarrhea occurs in malnourished infants, those with AIDS, and occasionally previously normal children. Even nondysenteric disease can be complicated by persistent illness.

Neurologic findings are among the most common extraintestinal manifestations of bacillary dysentery, occurring in as many as 40% of hospitalized infected children. Enteroinvasive *E. coli* can cause similar neurologic toxicity. Convulsions, headache, lethargy, confusion, nuchal rigidity, or hallucinations

may be present before or after the onset of diarrhea. The cause of these neurologic findings is not understood. In the past, these symptoms were attributed to the neurotoxicity of Shiga toxin, but it is now clear that that explanation is wrong. Seizures sometimes occur when little fever is present, suggesting that simple febrile convulsions do not explain their appearance. Hypocalcemia or hyponatremia may be associated with seizures in a small number of patients. Although symptoms often suggest central nervous system infection, and cerebrospinal fluid pleocytosis with minimally elevated protein levels can occur, meningitis due to shigellae is rare.

The most common complication of shigellosis is dehydration. Inappropriate secretion of antidiuretic hormone with profound hyponatremia may complicate dysentery, particularly when *S. dysenteriae* is the etiologic agent. Hypoglycemia and protein-loosing enteropathy are common. Other major complications, particularly in very young, malnourished children, include sepsis and disseminated intravascular coagulation. Given that shigellae penetrate the intestinal mucosal barrier, these events are surprisingly uncommon. Shigellae and sometimes other gram-negative enteric bacilli are recovered from blood cultures in 1–5% of patients in whom blood cultures are taken; because patients selected for blood cultures represent a biased sample, the risk of bacteremia in unselected cases of shigellosis is presumably lower. Bacteremia is more common with *S. dysenteriae* serotype 1 than with other shigellae. The mortality rate is high (~20%) when sepsis occurs.

S. dysenteriae serotype 1 infection is commonly complicated by hemolysis, anemia, and hemolytic-uremic syndrome. This syndrome is caused by Shiga toxin–mediated endothelial injury; *E. coli* that produce Shiga toxin (e.g., *E. coli* 0157:H7, *E. coli* 0111:NM, *E. coli* 026:H11) also cause hemolytic-uremic syndrome (Chapter 510).

Rectal prolapse, toxic megacolon or pseudomembranous colitis (usually associated with *S. dysenteriae*), cholestatic hepatitis, conjunctivitis, iritis, corneal ulcers, pneumonia, arthritis (usually 2–5 wk after enteritis), Reiter syndrome, cystitis, myocarditis, and vaginitis (typically with a blood-tinged discharge associated with *S. flexneri*) are uncommon events. Death is a rare outcome in well-nourished older children; malnutrition, illness in the 1st year of life, hypothermia, severe dehydration, thrombocytopenia, hyponatremia, renal failure, and bacteremia are common in children who die during bacillary dysentery. The rare syndrome of extreme toxicity, convulsions, extreme hyperpyrexia, and headache followed by brain edema and a rapidly fatal outcome without sepsis or significant dehydration (Ekiri syndrome or “lethal toxic encephalopathy”) is not well understood.

Diagnosis.

Although clinical features suggest shigellosis, they are insufficiently specific to allow confident diagnosis. Infection by *Campylobacter jejuni, Salmonella*, enteroinvasive *E. coli*, Shiga toxin–producing *E. coli* such as *E. coli* 0157:H7, *Yersinia enterocolitica, Clostridium difficile*, and *Entamoeba histolytica* as well as inflammatory bowel disease may cause confusion. Presumptive data supporting a diagnosis of bacillary dysentery include the finding of fecal leukocytes (confirming the presence of colitis), fecal blood, and demonstration in peripheral blood of leukocytosis with a dramatic left shift (often with more bands than segmented neutrophils). The total peripheral white blood cell count is usually 5,000–15,000 cells/mm^3 , although leukopenia and leukemoid reactions occur.

Culture of both stool and rectal swab specimens optimizes the chance of diagnosing *Shigella* infection. Culture media should include MacConkey agar as well as selective media such as xylose-lysine deoxycholate (XLD) and SS agar. Transport media should be used if specimens cannot be cultured promptly. Appropriate media should be used to exclude *Campylobacter* and other agents. Studies of outbreaks and illness in volunteers show that the laboratory is often not able to confirm the clinical suspicion of shigellosis even when the pathogen is present. Although additional tools to improve diagnosis (e.g., gene probes) are being developed, the diagnostic inadequacy of cultures makes it incumbent on the clinician to use judgment in the management of clinical syndromes consistent with shigellosis. In children who appear to be toxic, blood cultures should be obtained; this is particularly important in very young or malnourished infants because of their increased risk of bacteremia.

Treatment.

As with gastroenteritis of other causes, the first concern about a child with suspected shigellosis should be for fluid and electrolyte correction and maintenance (Chapters 46 and 48.1). Nutrition is a key concern in areas where malnutrition is common. A high protein diet during convalescence enhances growth in the following 6 mo. A single large dose of vitamin A (200,000?IU) lessens severity of shigellosis in settings where vitamin A deficiency is common. Drugs that retard intestinal motility (e.g., diphenoxylate hydrochloride with atropine [Lomotil] or loperamide [Imodium]) should not be used because of the risk of prolonging the illness.

The next concern is a decision about the use of antibiotics. Although some authorities recommend withholding antibacterial therapy because of the self-limited nature of the infection, the cost of drugs, and the risk of emergence of resistant organisms, there is a persuasive logic in favor of empirical treatment of all children in

whom shigellosis is strongly suspected. Even if not fatal, the untreated illness may cause a child to be quite ill for 2 wk or more; chronic or recurrent diarrhea may ensue. Malnutrition may develop or worsen during prolonged illness, particularly in children in developing countries. The risk of continued excretion and subsequent infection of family contacts further argues against the strategy of withholding antibiotics.

There are major geographic variations in antibiotic susceptibility of shigellae. In the United States, shigellae are so frequently resistant to ampicillin that it is not appropriate for empirical therapy. However, oral ampicillin (100?mg/kg/24?hr divided qid PO) may be used if the strain is known to be susceptible. Amoxicillin, because of better gastrointestinal absorption, is less effective than ampicillin for treatment of ampicillin-sensitive strains. Many regions of the United States now harbor strains that are also resistant to trimethoprim-sulfamethoxazole (TMP-SMZ). Cefixime (8?mg/kg/24?hr divided bid PO) or ceftriaxone (50?mg/kg/24?hr as a single daily dose IV or IM) can be used for empirical therapy. Nalidixic acid (55?mg/kg/24?hr divided qid PO) is also an acceptable alternative drug. Quinolones such as ciprofloxacin, norfloxacin, or ofloxacin, which have been recommended for use in persons =18 yr of age, are not routinely used for children because of the putative risk of arthropathy. Use of these agents is reserved for seriously ill children with bacillary dysentery due to an organism that is suspected or known to be resistant to other agents. Treatment is typically for a 5-day course. Oral first- and second-generation cephalosporins are inadequate as alternative drugs despite in vitro susceptibility.

Treatment of patients suspected on clinical grounds of having *Shigella* infection should be initiated when first examined. Stool culture is obtained to exclude other pathogens and to assist in antibiotic changes should a child fail to respond to empirical therapy. A child who has typical dysentery and who responds to initial empirical antibiotic treatment should be continued on that drug for a full 5-day course even if the stool culture is negative. The logic of this recommendation is based on the difficulty of culturing *Shigella* from stools. In a child who fails to respond to therapy of a dysenteric syndrome in the presence of initially negative stool culture results, cultures should be retaken and the child re-evaluated for other possible diagnoses.

Prevention.

Two simple measures decrease the risk of shigellosis in children. The first is to encourage prolonged breast-feeding of infants. Breast-feeding decreases the risk of symptomatic

shigellosis and lessens its severity in those infants who acquire infection despite breast-feeding. The second measure is to educate families and child-care center personnel in handwashing techniques, especially after defecation and before food preparation and consumption. **REFERENCES**

Chapter 183 - *Escherichia coli*

Theresa J. Ochoa
Thomas G. Cleary

Escherichia coli are important causes of enteric infections as well as urinary tract infections (Chapter 530), sepsis and meningitis in the newborn (Chapter 98), and bacteremia and sepsis in immunocompromised patients (Chapter 164) and in patients with intravascular devices (Chapter 165).

Etiology.

E. coli species are members of the Enterobacteriaceae family. They are oxidase-positive, facultatively anaerobic, gram-negative bacilli. Fermentation of lactose is variable. Five groups of diarrheagenic *E. coli* have been characterized on the basis of clinical, biochemical, and molecular-genetic criteria (Table 183–1): (1) **enterotoxigenic *E. coli* (ETEC)** produce secretory enterotoxins; (2) **enteroinvasive *E. coli* (EIEC)** are capable of invading intestinal epithelial cells and causing a dysenteric illness; (3) **enteropathogenic *E. coli* (EPEC)** are defined by their pattern of adherence to tissue culture cells and their ability to produce a characteristic alteration in the microvillus membrane, the “attaching and effacing” lesion; (4) **shigatoxin-producing *E. coli* (STEC)**, also known as enterohemorrhagic *E. coli* (EHEC), *Shiga*-like toxin-producing *E. coli* (SLT-EC) and verotoxin-producing

TABLE 183-1 -- **Clinical Characteristics and Pathogenesis of Diarrheogenic *Escherichia coli***

E. coli (VTEC) produce Shiga toxins (Stx) and cause diarrhea, hemorrhagic colitis, and hemolytic-uremic syndrome (HUS); (5) **enteroaggregative *E. coli* (EAggEC)** adhere in vitro to HEp-2 cells in a characteristic aggregative manner and are associated with persistent diarrhea in children.

Epidemiology.

In the developing world, the various diarrheogenic serogroups of *E. coli* cause frequent infections in the first few years of life. They occur with increased frequency during the warm months in temperate climates and during rainy season months in tropical climates. Most *E. coli* strains (except STEC and perhaps some EPEC) require a large inoculum of organisms to induce disease; person-to-person spread is atypical, but food-borne or water-borne illness is common. Infection is most likely when food-handling or sewage-disposal practices are suboptimal.

ETEC are a major cause of infantile diarrhea in the developing countries, as well as important etiologic agents of traveler's diarrhea. They account for approximately 20–30% of diarrhea episodes in the developing world.

EIEC are mostly described in outbreaks; however, endemic disease occurs in developing countries where these bacteria can be isolated with relatively high frequency. In the developing world as many as 5% of sporadic diarrhea episodes

and 20% of bloody diarrhea cases may be caused by EIEC strains.

EPEC are a major cause of infant diarrhea and mortality in developing countries, primarily in children <2 yr of age. In developed countries EPEC are responsible for occasional outbreaks in daycare centers and pediatric wards. Several studies have shown that breast-feeding is protective against diarrhea due to EPEC.

STEC infections may be asymptomatic. Very young children are not a target group of STEC; rather, severe and complicated illness occurs most often among children from 6 mo to 10 yr of age. The elderly may also be severely affected. STEC are transmitted person to person as well as by food and water, because ingestion of a low number of these organisms is sufficient to cause disease. Poorly cooked hamburger is a common cause of food-borne outbreaks, although many other foods including apple cider, lettuce, mayonnaise, salami, dry fermented sausage and unpasteurized dairy products have also been incriminated. Although most outbreaks of STEC-associated diarrhea in the Northern hemisphere have been attributed to strains of serotype 0157:H7, many other serotypes have been associated with outbreaks and sporadic cases of severe disease.

EAggEC asymptomatic excretion rates can be high. EAggEC are associated with persistent (lasting >14 days) pediatric diarrhea in developing countries, most prominently in children >12 mo of age. EAggEC are etiologic agents in AIDS-associated chronic diarrhea and traveler's diarrhea.

Pathogenesis.

Because *E. coli* organisms are normal fecal flora, demonstration of virulence characteristics is the usual way by which the diarrheogenic *E. coli* are defined. The mechanism by which *E. coli* produces diarrhea typically involves adherence of organisms to a glycoprotein or glycolipid receptor, followed by production of some noxious substance that injures gut cells or disturbs their function. The genes for virulence properties and for antibiotic resistance are often carried on transferable plasmids, pathogenicity islands, or bacteriophages.

ETEC cause few or no structural alterations in the gut mucosa. Diarrhea is caused by colonization of the small intestine and subsequent elaboration of enterotoxins. ETEC secrete a **heat-labile enterotoxin (LT)** or a **heat-stable enterotoxin (ST)**, or both. LT, a large molecule consisting of five receptor-binding subunits and one enzymatically active subunit, is structurally, functionally, and immunologically related to cholera toxin produced by *Vibrio cholerae*. LT stimulates adenylate cyclase, resulting in increased cyclic adenosine monophosphate. ST is a small molecule not related to LT or cholera toxin. ST stimulates guanylate cyclase, resulting in increased cyclic guanosine monophosphate. A large proportion of ETEC strains also produce EAST1, a heat-stable toxin similar to ST, which was originally identified in EAggEC strains

Colonization of the intestine requires fimbrial colonization factor antigens (CFAs), which promote adhesion to the intestinal epithelium. The most prevalent colonization factors are CFA/I, CFA/II and CFA/IV. CFAs are composed of distinct *E. coli* surface antigens (CS), expressed in different combinations. A large proportion of ETEC strains produce a type IV pilus called longus, which functions as a colonization factor and is found among several gram-negative bacterial pathogens. The binding of enterotoxigenic invasion protein A (Tia), a 25-kd outer membrane protein, to host epithelial cells is mediated at least in part through heparan sulfate proteoglycans; ETEC belong on the growing list of pathogens that use these ubiquitous cell surface molecules as receptors.

Of the >180 *E. coli* serogroups, only a relatively small number typically are ETEC; these serogroups (06, 08, 015, 020, 025, 027, 063, 078, 080, 085, 0115, 0128ac [but not subgroups 0128ab or 0128ad], 0139, 0148, 0153, 0159, and 0167) are generally different from those found in the other diarrhea-associated *E. coli*.

EIEC cause colonic lesions with ulcerations, hemorrhage, and infiltration of polymorphonuclear leukocytes and mucosal and submucosal edema. EIEC strains behave like shigellae in their capacity to invade gut epithelium and produce a dysentery-like illness. The invasive process involves (1) initial entry into cells, (2) intracellular multiplication, (3) intracellular and intercellular spread, and (4) host-cell killing. All bacterial genes necessary for entry into the host cell are clustered within a 30-kb region of a large virulence plasmid, also found in *Shigella*. This region carries the *ipa* and *ipg* genes encoding the entry-mediating proteins and their individual intrabacterial chaperones, and the *mxi* and *spa* genes, which code for proteins forming a type III secretion apparatus required for secretion of the invasins (IpaA-D and IpgD). IpaB and IpaC have been identified as the primary effector proteins of epithelial cell invasion. The type III secretion apparatus is found in many other pathogenic gram-negative bacteria. Its major function is to transport proteins from the bacteria cytoplasm into the host cell plasma membrane and cytoplasm upon contact with host cells.

EIEC encompass a small number of serogroups (028ac, 029, 0124, 0136, 0143, 0144, 0152, 0164, 0167, and some untypable strains). These serogroups have lipopolysaccharide (LPS) antigens related to *Shigella* LPS, and, like shigellae, the organisms are nonmotile (they lack H or flagellar antigens) and are usually nonlactose fermenting.

EPEC are associated with blunting of villi, inflammatory changes, and sloughing of superficial mucosal cells; these lesions are found from the duodenum through the colon. EPEC induce a characteristic **attaching and effacing** (A/E) histopathologic lesion, which is defined by the intimate attachment of bacteria to the epithelial surface and effacement of host cell microvilli. Factors responsible for the A/E lesion formation are encoded by the locus of enterocyte effacement (LEE) which is a pathogenicity island that contains the genes for (1) the type III secretion system, (2) the translocated intimin receptor (Tir) and intimin, and (3) the *E. coli*–secreted proteins (EspA-B-D).

EPEC pathogenesis involves three distinct stages. The first stage is the initial adherence of the bacteria to the host's intestinal epithelium in a pattern known as localized adherence, mediated in part by the type IV bundle forming pilus (BFP) encoded in the EAF plasmid. The second stage involves the production and translocations of bacterial proteins through a “needle complex” or type III secretion

system. Filamentous appendages made of EspA form a physical bridge between the bacteria and the host cell for the translocations of bacterial effectors (EspB, EspD, Tir). EspB and EspD form pores in the host's cell membrane. The third stage is characterized by intimate bacterial attachment to the host cell, enterocyte effacement, and pedestal formation. Tir is injected into host cells by way of this conduit. Tir moves to the surface of host cells where it is bound by a bacterial outer membrane protein intimin (encoded by the *eae* gene). Intimin-Tir binding triggers polymerization of actin and other cytoskeletal components at the site of attachment. Other bacterial effectors include a mitochondrial-associated protein (Map) with membrane-potential disrupting activity and EspF, a protein that disrupts the intestinal barrier function and induces host cell death.

Some serogroups are associated with localized adherence and are EAF probe positive (055, 086, 0111, 0119, 0125, 0126, 0127, 0128ab, and 0142), whereas others are nonadherent or diffusely adherent to HEp-2 cells and are usually EAF probe negative (018, 044, 0112, and 0114). There is more evidence that EPEC with localized adherence are true enteropathogens than there is for those with diffuse adherence.

STEC affect the colon most severely. These organisms cause edema, fibrin deposits, hemorrhage in the submucosa, mucosal ulceration, neutrophil infiltration, and microvascular thrombi. Pseudomembranous colitis may be seen. **Shiga toxins** are considered to be the cardinal virulence factor of STEC. There are two major toxin types, Stx1 and Stx2. Some STEC produce only Stx1 and others only Stx2, but most STEC produce both toxins. Stx1 (or SLT-I or VT-1) is essentially identical to Shiga toxin, the protein synthesis-inhibiting exotoxin of *Shigella dysenteriae* serotype 1, whereas Stx2 (or SLT-II or VT-2) and variants of Stx2 are more distantly related. Each toxin is composed of a single A subunit noncovalently associated with a pentamer composed of identical B subunits. The B subunits bind to globotriaosylceramide (Gb_3), a glycosphingolipid receptor on host cells. The A subunit is taken up by endocytosis. The toxin target is the 28S rRNA, which is depurinated by the toxin at a specific adenine residue, causing protein synthesis to cease and affected cells to die. Stx enters the systemic circulation after translocation across the intestinal epithelium and damages endothelial cells. This causes activation of the coagulation cascade, formation of microthrombi, intravascular hemolysis, and ischemia. STEC induce pro-inflammatory cytokines. Clinical outcome of STEC infection depends on the *stx* genotype of the infecting strain. Stx2 genotype is associated with a more severe disease.

STEC adhere to intestinal cells and produce attaching-effacing lesions like those seen with EPEC. Most pathogenic strains of STEC contain the locus for enterocyte effacement. Most STEC strains also carry a large plasmid encoding proteins such as the enterohemolysin (EhyA), an extracellular serine protease (EspP) and a STEC autoagglutinating adhesin (Saa), which may be accessory virulence factors.

The most common serotypes are *E. coli* O157:H7, *E. coli* 0111:NM, and *E. coli* 026:H11, although a number of other STEC

serotypes have also been described. Some *E. coli* 026:H11 and *E. coli* 0111:NM strains produce Shiga toxin, but others do not.

EAggEC form a characteristic mucous biofilm on the intestinal mucosa and induce shortening of the villi, hemorrhagic necrosis, and inflammatory responses. The proposed model of pathogenesis of EAggEC involves three phases: adherence to the intestinal mucosa by way of the aggregative adherence fimbriae (AAF); enhanced mucous production; and production of toxins and inflammation that results in damage of the mucosa and intestinal secretion. Diarrhea caused by EAggEC is predominantly secretory. The intestinal inflammatory response (elevated fecal lactoferrin, IL-8 and IL-1ß) may be related to growth impairment and malnutrition.

Putative EAggEC virulence factors include aggregative adherence fimbriae (AAF/I and AAF/II), a 108-kd plasmid-encoded cytotoxin (Pet), hemolysins, various outer membranes proteins, and an enterotoxin designated as enteroaggregative *E. coli* heat stable toxin 1 (EAST 1). The EAST 1 gene, *astA*, is also present in other diarrheogenic *E. coli* and some other human enteric pathogens.

Strains of *E. coli* categorized as EAggEC belong to a diverse range and combination of O and H serotypes. Some EAggEC, however, do not express O antigens, are nonmotile or untypable.

Clinical Manifestations.

The clinical features of *E. coli*-associated diarrhea vary in relation to the different mechanisms of disease production.

ETEC are a major cause of dehydrating infantile diarrhea in the developing world. The typical signs and symptoms include explosive watery, nonmucoid, nonbloody diarrhea, abdominal pain, nausea, vomiting, and little or no fever. The illness is usually self-limited in 3–5 days, but occasionally lasts >1 wk.

EIEC infections present most commonly as watery diarrhea, which can be indistinguishable from the secretory diarrhea seen with ETEC. A minority of patients experience a dysentery syndrome, manifested as blood, mucus, and leukocytes in the stools, with fever, systemic toxicity, crampy abdominal pain, tenesmus, and urgency.

EPEC generally cause acute diarrhea, but severe cases can lead to protracted disease. In addition to profuse watery, nonbloody diarrhea with mucus, vomiting and low-grade fever are common symptoms. Chronic diarrhea and malnutrition can occur in infants in the developing world.

STEC have been shown to cause a wide spectrum of diseases. Patients develop intestinal symptoms ranging from mild diarrhea to severe hemorrhagic colitis. The gastrointestinal illness is characterized by abdominal pain with diarrhea that is initially watery but within a few days becomes blood-streaked or grossly bloody. Although this pattern resembles that of shigellosis or EIEC disease, it differs in that fever is an uncommon manifestation. Most individuals infected with STEC recover from the infection without further complication. However, 5–10% of children go on to develop systemic complications such as hemolytic-uremic syndrome, characterized

by acute renal failure, thrombocytopenia, and hemolytic anemia. The elderly may also develop HUS or thrombotic thrombocytopenic purpura.

EAggEC typical illness is manifested by watery, mucoid, secretory diarrhea with low-grade fever and little or no vomiting. One third of patients have grossly bloody stools. The watery diarrhea may persist =14 days. EAggEC is associated with growth retardation in infants and malnutrition.

Diagnosis.

The clinical features of illness are seldom distinctive enough to allow confident diagnosis, and routine laboratory studies are of very limited value. Diagnosis currently depends heavily on laboratory studies that are not readily available to practitioners.

The diagnosis of diarrheogenic *E. coli* infection can be made based on (1) initial isolation of the bacteria from stool cultures, (2) biochemical criteria (e.g., fermentation patterns), (3) detection of the bacteria serogroup/serotype, (4) animal models (e.g., Sereny test for invasiveness in EIEC), (5) tissue culture (e.g., HEp2-cells assays for EPEC and EAggEC), (6) detection of antibodies against specific virulence factors (e.g., intimin, EspA, EspB), and (7) identification of specific virulence factors of the bacteria by phenotypic (e.g., toxins) or genotypic (e.g. *ipa, eae, ehyA* genes) detection assays.

DNA probes for genes encoding the various virulence traits are the best diagnostic tests, but are currently available only as a research tool. Therefore, suspected organisms should be forwarded to reference or research laboratories for definitive evaluation. Such efforts are seldom necessary, but they may be important for correct diagnosis when a child has severe or life-threatening complications or for outbreak investigation. DNA probes for genes encoding the various virulence factors are now available for all the diarrheogenic *E. coli.* However, because of the emergence of different combinations of virulence gene sequences (genetic profiles) found in the *E. coli* strains (that might have been transferred horizontally in the intestine and/or environment), multiple phenotypic and genotypic characteristics need to be tested in each strain.

Practical, non-DNA–dependent, methods for routine diagnosis of diarrheogenic *E. coli* have been developed primarily for the STEC. Serotype O157:H7 is suggested by failure to ferment sorbitol on MacConkey sorbitol medium; latex agglutination confirms that the organism contains O157 LPS. Other STEC can be detected in routine hospital laboratories using commercially available enzyme immunoassay or latex agglutination to detect Shiga toxins.

Other laboratory data are at best nonspecific indicators of etiology. Fecal leukocyte examination of the stool is frequently positive with the EIEC but negative with all other diarrheogenic *E. coli*. With EIEC and STEC there may be an elevated leukocyte count with a left shift. Fecal lactoferrin, IL-8 and IL-1ß can be used as inflammatory markers. Electrolyte changes are nonspecific, reflecting only fluid loss.

Treatment.

The cornerstone of proper management is related to fluid and electrolyte therapy. In general, this therapy should include oral replacement and maintenance with rehydration solutions such as those specified by the World Health Organization. Early refeeding (within 8–12?hr of initiation of rehydration) with breast milk or infant formula should be encouraged. Prolonged withholding of feeding frequently leads to chronic diarrhea and malnutrition.

Specific antimicrobial therapy of diarrheogenic *E. coli* is problematic because of the difficulty of making an accurate diagnosis of these pathogens and the unpredictability of antibiotic susceptibilities. ETEC respond to antimicrobial agents such as trimethoprim-sulfamethoxazole (TMP-SMZ) when the *E. coli* strains are susceptible. However, other than for a child recently returning from travel in the developing world, empirical treatment of severe watery diarrhea with antibiotics is seldom appropriate. EIEC infections are usually treated before the availability of culture results because the clinician typically suspects shigellosis and begins empirical therapy. If the organisms are susceptible, TMP-SMZ is an appropriate choice. Although treatment of EPEC infection with TMP-SMZ intravenously or orally for 5 days is effective in speeding resolution, the lack of a rapid diagnostic test makes treatment decisions difficult. The STEC represent a particularly difficult therapeutic dilemma. The data suggest that antibiotic treatment may increase the risk of hemolytic-uremic syndrome (Chapter 510). Some data suggest that ciprofloxacin, which is seldom used in children, is useful for EAggEC traveler's diarrhea.

Antibiotic resistance is often encoded on the same plasmids that carry virulence proteins and continues to make rational decisions about antibiotic therapy difficult. Because emergence

of resistance to widely used regimens is typical, new antimicrobial agents must continue to be evaluated.

Complications.

The major complications of diarrheal illness are related to dehydration and electrolyte loss. Some complications are related to specific pathogens. EPEC and EAggEC are likely to cause persistent diarrhea and malnutrition. Infection with STEC can be associated with the hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura (Chapter 510).

Prevention.

In the developing world, prevention of disease caused by diarrheogenic *E. coli* is probably best done by maintaining prolonged breast-feeding, paying careful attention to personal hygiene, and following proper food- and water-handling procedures. People traveling to these places can be best protected by consuming only processed water, bottled beverages, breads, fruit juices, fruits that can be peeled, or foods that

are served steaming hot.

Prophylactic antibiotic therapy, although effective in adult travelers, has not been studied in children and is not recommended. Public health measures, including sewage disposal and food-handling practices, have made pathogens that require large inocula to produce illness relatively uncommon in industrialized countries. Food-borne outbreaks of STEC are a problem for which no adequate solution has been found. During the occasional hospital outbreak of EPEC disease, attention to enteric isolation precautions and cohorting may be critical.

The nature of protective immunity is not fully understood and no vaccines are available for clinical use. There are several vaccine candidates based on bacterial toxins or colonization factors that are being studied in animals.

Chapter 184 - Cholera (*Vibrio cholerae*)

Gloria P. Heresi
James R. Murphy

Cholera remains an important public health problem for many poorer communities and an episodic problem for richer communities; the disease is responsible for significant morbidity and mortality worldwide with an estimated 5–7 million cases and >100,000 deaths/yr. The disease can cause the death of a previously healthy individual in hours and must be addressed as an emergency.

The 1990s witnessed the reintroduction of epidemic cholera into the Americas, the emergence of a new epidemic strain, and an outbreak with an extraordinary death rate (12,000 deaths among 70,000 cases). The genome of a representative *V. cholerae* was published in 2000. The long history of studies of cholera is marked with numerous significant medical findings, including Snows' 1850s seminal studies of epidemiology and the studies that led to modern rehydration practices that have saved countless lives. Yet unknown facets of the biology of the organism continue to be discovered and *V. cholerae* continues to cause substantial suffering.

Etiology.

The cause of cholera is *V. cholerae*, a gram-negative, non–spore-forming, motile, slightly curved rod (1.5–3.0 × 0.5?µm), with a polar flagellum. *V. cholerae* includes pathogenic and non-pathogenic strains; *V. cholera* O1 and O139 are responsible for causing disease. The two **biogroups (or biotypes)** of *V. cholerae* O1 are differentiated as **classic** and **El Tor** based on hemolysin, hemagglutination, susceptibility to polymyxin B, and susceptibility to bacteriophages. They are also subdivided into **serogroups (or serovars)** based on O antigens. *V. cholerae* O1 has two major O antigenic types (**Ogawa** and **Inaba**) and an unstable intermediate type **(Hikojima)**. *V. cholerae* O139 is closely related to the El Tor biotype. Recently, the genome of *V. cholerae* O1 biotype El Tor was published. The genome comprises two circular chromosomes: a larger chromosome of 3 million bp and a smaller chromosome of 1.07 million bp.

Epidemiology.

Cholera exists in sporadic, endemic, epidemic, and pandemic forms. The transition

from epidemic to endemic may relate to a population acquiring immune resistance. During epidemics, high rates of intrafamilial spread occur (up to 50%). Transmission is usually by fecal-oral spread with contaminated water as the main vehicle but contaminated food and utensils may also play important roles as may houseflies. Water also serves as an environmental reservoir of *V. cholerae*.

Humans are the only known vertebrate reservoirs of *V. cholerae*. However, evidence is scarce that persistent carriers are responsible for intraepidemic maintenance. Other possible explanations for intraepidemic maintenance include the existence of nonculturable but viable strains in water and the existence of O antigen–deficient organisms that may gain O antigen by a variety of means.

A notable feature of cholera is the occurrence of global epidemics or pandemics. In pandemics, an O1 vibrio emerges from an Asian site and spreads globally over ensuing years or decades and then wanes. This pattern was first identified in 1831 when the second pandemic of cholera reached England. In 1961 *V. cholerae* O1 biotype El Tor began spreading from a focus in Indonesia. This marked the start of the still ongoing seventh pandemic. In January 1991, this pandemic strain was found in Peru, marking the first time in >100 yr that epidemic cholera existed in the Americas. At least 20 countries in Latin America have reported cholera cases resulting from this pandemic; Latin American cases exceed 1,000,000 and deaths exceed 10,000. In 1973, a focus of *V. cholerae* O1 biotype El Tor was identified in the Gulf of Mexico. This strain is not the El Tor responsible for the seventh pandemic; it differs by ribotype and restriction fragment length polymorphisms, for example.

In 1992, an epidemic cholera-like disease occurred in southern India. The agent was a *V. cholera* that received the designation *V. cholerae* O139, Bengal. This *V. cholera* was the first non–O1 vibrio with demonstrated epidemic-causing capability. It rapidly spread through the Indian subcontinent raising fears that an eighth pandemic was starting that might run concomitantly with the seventh. For unknown reasons, O139 has not continued its epidemic spread. O139 Bengal is derived genetically from the O1 El Tor strain responsible for the seventh pandemic but has changed its antigenic structure in a way that immunity acquired by exposure to O1 vibrios is ineffective. Thus, many populations and all age groups, even in cholera endemic regions, are susceptible to O139 disease.

In 1994, over 20,000 people died in a 4-wk period from an outbreak of cholera during a Rwandan refugee crisis. The magnitude of this disaster, which recapitulates historical cholera, establishes the continued virulence of the vibrios and what happens if medical interventions are unavailable, delayed, or denied.

Pathogenesis.

Severe cholera results from the voluminous loss by diarrhea of fluid isotonic with plasma and with high concentrations of bicarbonate and potassium; these outcomes result

from the actions of toxins produced by *V. cholerae* that have colonized the upper small bowel. Colonization usually requires the ingestion of a large number of viable vibrios (>~10^8 viable units), in part, because the organisms are killed by acid environments including the normal stomach. Under conditions in which gastric acidity is neutralized or absent (i.e., hypochlorhydria) the infectious dose is about 10,000-fold less. Once in the upper small intestine, the organisms must associate with the mucosa and produce toxin if disease is to follow. Association with the mucosa is facilitated by bacterial motility, chemotaxis, and the production of a protease that facilitates penetration of the mucus overlying the epithelium.

The primary mechanism of fluid loss is activation of adenylyl cyclase at the cytoplasmic surface of the basolateral membrane by the enterotoxin, **cholera toxin** (CT). To accomplish this, CT must enter the intestinal epithelial cell at the apical end and transit to the basolateral membrane. This is effected by CT co-opting the machinery for membrane traffic endogenous to the epithelial cell. CT trafficks as an intact protein through two unique pathways: transcytosis and retrograde movement through the Golgi cisternae to the endoplasmic reticulum. CT comprises an enzymatically active A subunit and five cell-binding B subunits. The structural genes for CT are encoded within a lysogenic phage (CTx?) that is integrated into the large chromosome. Induction of expression of CT production follows an interaction of *V. cholerae* with the intestinal microenvironment. The receptor for subunit B is the ganglioside GM_1 . The A1 portion of A subunit is an adenosine diphosphate-ribosyltransferase that activates the a-subunit of the stimulatory G protein to bind and activate adenylate cyclase, resulting in prolonged elevation of cyclic adenosine monophosphate (cAMP) levels. The high cAMP level causes a decrease in active absorption of sodium and chloride by villous cells and an increase in active secretion of chloride by crypt cells. *V. cholerae* produces additional enterotoxins (zonula occludens toxin [*zot*], accessory cholera enterotoxin [*ace*]) that are of lesser clinical importance.

It was recently established that the propagation of the bacteriophage that bears the CT gene is influenced by environmental factors such as temperature, sunlight, and salinity. Knowledge of the switching on of these and similar genes may provide resolution to the long-standing issue of how cholera re-emerges from environmental sources to cause epidemics.

Clinical Manifestations.

Toxigenic strains of *V. cholera* O1 and O139 cause a broad spectrum of disease. Most infected people are asymptomatic, about one fourth present with mild to moderate disease, and 2–5% developed severe cholera. The hallmark of cholera is massive loss of fluids and electrolytes. Watery diarrhea and vomiting develop after an incubation period of 6?hr–5 days (average, 2–3 days). Low-grade fever occurs in some children. In severe cases, patients have profuse, painless, watery diarrhea with a rice-water consistency and a fishy odor, sometimes with flecks of mucus but no blood. The fluid and electrolyte losses lead to thirst and tachycardia, followed by tachypnea, irritability, a sunken anterior fontanel, poor skin turgor, and progress to circulatory collapse, stupor, and renal failure if untreated. Diarrhea may be so massive that vascular collapse occurs <24?hr after onset. Fluid losses may continue for as long as 1 wk.

Laboratory Findings.

Changes related to dehydration and electrolyte loss are common. Hemoconcentration is manifested with increased serum protein, elevated hematocrit, and increased serum specific gravity. Hyponatremia, hypokalemia, and acidosis are often present in moderate and severe cases. Fecal leukocytes are not present because *V. cholera* does not invade the mucosa.

Diagnosis.

In individual cases, diagnosis of cholera remains primarily clinical. In epidemiologic investigations, laboratory confirmation is required. In endemic areas, a child with severe watery diarrhea should be considered to have a possible case of cholera pending laboratory investigations, and treatment should be started. In the United States, the diagnosis should be suspected in any child with severe watery diarrhea and a history of recent travel to an endemic area.

Two selective media are used for culturing *V. cholerae*: thiosulfate-citrate-bile-sucrose (TCBS) and tellurite-taurocholate-gelatin agar (TTGA). The gold standard for cholera diagnosis remains stool culture on TCBS medium. On TCBS, *V. cholerae* appears as large smooth yellow colonies against the bluish-green background of the medium. On TTGA, the colonies are small and opaque, with a zone of cloudiness around them. Colonies of O139 strains grown on TTGA are grayish opaque with dark centers. Biotyping of *V. cholerae* into classic or El Tor is made on the basis of direct hemagglutination with chicken or sheep red blood cells (i.e., El Tor strains agglutinate), sensitivity to polymyxin B (i.e., classic strains are sensitive), or susceptibility to cholera-phage group IV (i.e., classic strains are susceptible). Recently, rapid diagnosis techniques using DNA-based methods have been developed; polymerase chain reaction (PCR) using primers with high sensitivity and specificity for the ctxA gene and an outer membrane protein, OmpW gene, are described. Use of PCR seems a promising method to improve detection of *V. cholerae* in environmental sources. Immunoassays as rapid diagnostics are under evaluation.

Treatment.

The mainstay of treatment for cholera is fluid and electrolyte replacement. Oral or parenteral rehydration therapy should be initiated as soon as the diagnosis is suspected. The World Health Organization Oral Rehydration Solution (WHO-ORS) contains per liter 90?mmol of Na^+ , 20?mmol of K^+ , 80?mmol of Cl^- , 111?mmol of glucose, and 30?mmol of bicarbonate (citrate can be substituted for bicarbonate). Oral rehydration given ad libitum is the treatment of choice, unless the child is obtunded, has an ileus, or is in shock; in these cases, intravenous saline or lactated Ringer solution rather than oral rehydration is appropriate. Vomiting is not a contraindication to oral rehydration. Although all patients with cholera should be carefully monitored, attention to intake and output is especially important for infants. Food should be restarted as soon as deficits are replaced to minimize the nutritional impact of the illness; refeeding does not affect purging rates or the duration of diarrhea. The success of oral rehydration was well demonstrated when epidemic cholera arrived in Peru in 1991; the mortality rate was <1%.

Rehydration is the most important treatment. However, antibiotics are useful in shortening the duration of illness, reducing the period of excretion of the organisms, and decreasing the requirements for fluid replacement. Antimicrobial therapy should be considered for patients with moderate or severe disease. Oral tetracycline (50?mg/kg/24?hr divided qid PO for 3 days; maximum: 2?g/24?hr) or doxycycline (5?mg/kg PO as a single dose, maximum: 200?mg/24?hr) are the drugs of choice for cholera due to *V. cholera* O1 and O139. For children <9 years of age, the use of tetracycline is not recommended. In resistant strains or children <9 years old, trimethoprim-sulfamethoxazole (8–10?mg/kg/24?hr of trimethropin and 40?mg/kg/24?hr of sulfamethoxazole, divided bid PO), erythromycin (40?mg/kg/24?hr; maximum: 2?g/24?hr), or furazolidone (5–8?mg/kg/24?hr, maximum: 400?mg) may be used. Resistance to tetracycline and other antimicrobials is increasing. Studies show a lower prevalence of antimicrobial resistance in O139 serotypes compared with O1 serotypes. Some African isolates (i.e., from Uganda) are resistant to TMP-SMZ, tetracycline, chloramphenicol, ampicillin, and streptomycin. Quinolones are effective for infection due to *V. cholera* O1 and O139 but they are not recommended in patients <18 years. Recent data show increased resistance to norfloxacin of *V. cholera* O1 El Tor. Antibiotic resistance

evaluations should be performed of isolates from sporadic cases and representative cases from an epidemic.

Complications.

Lethargy, seizures, altered consciousness, fever, hypoglycemia, hyperglycemia, and death occur more frequently in children than in adults. Inadequate fluid and electrolyte replacement may lead to acute tubular necrosis. In severely ill children with potassium depletion and acidosis, hypokalemic arrhythmia can cause sudden death. Children with low potassium levels can develop paralytic ileus and abdominal distention that can make oral rehydration impossible. In as many as 10% of small children, prolonged drowsiness, coma, or seizures occur. When the seizures are associated with hypoglycemia, they are often followed by coma and death; in one study, 14.3% of children with cholera complicated by hypoglycemia died, compared with 0.7% of children without hypoglycemia. After dehydration, hypoglycemia is the most common life-threatening consequence of cholera in children. Hyperglycemia can be caused by secretion of epinephrine, norepinephrine, cortisol, glucagon, and C peptide in response to the stress of hypovolemia. Pulmonary edema occurs in some children, probably because of fluid overload during rehydration. Transient tetany may occur during correction of electrolyte imbalances. In children treated with excessive sugar and salt, hypernatremia can be observed. Despite its high sodium content, WHO-ORS is not associated with hypernatremia if used properly; it can be used to treat children with hypernatremic dehydration.

Prevention.

The most practical method of preventing life-threatening cholera in infants is prolonged breast-feeding. Safe food and water and proper handling of sewage are long-term solutions. Cost, ignorance, and politics have kept these basic needs from being met. The development of an improved vaccine is a high priority.

VACCINE.

The only currently approved cholera vaccine in the United States is made of phenol-killed organisms administered parenterally as a two-dose primary series followed by boosters every 6 mo to maintain immunity. This vaccine has about 50% efficacy by 3–6 mo after vaccination, does not protect against O139 vibrios, and is highly reactogenic (i.e., pain, erythema, local induration, fever, headaches). This vaccine should be used only in very high-risk persons (e.g., those with achlorhydria) with a very high probability of exposure. It is not recommended for children <6 mo of age. Travelers to areas endemic for cholera should take appropriate food precautions. Visitors to countries reporting cholera who follow common tourist itineraries and who use standard accommodations are at low risk of infection. Outside of the United States, two additional vaccines may be readily available: an oral killed whole cell cholera toxin recombinant B subunit vaccine, with 80–85% protection through 6 mo, and an oral live attenuated *V. cholerae* (CVD 103?HgR) vaccine, with 62–100% efficacy through 6 mo. Both products have markedly reduced reactogenicity compared with the product available in the United States but neither protects against O139 vibrios.

Chapter 185 - *Campylobacter*

Gloria P. Heresi
James R. Murphy

The genus *Campylobacter* includes more than 12 species. Those known or considered pathogenic for humans include *C. jejuni, C. fetus, C. coli, C. hyointestinalis, C. lari, C. upsaliensis, C. concisus, C. sputorum, C. rectus, C. mucosalis, C. jejuni* subspecies *doylei, C. curvus, C. gracilis*, and *C. cryaerophila*. Additional *Campylobacter* species have been isolated from clinical specimens, but their roles as pathogens have not been proved. *C. jejuni* and *C. coli* are the most important pathogens of the genus. More than 90 serotypes of *C. jejuni* have been identified. *C. jejuni* infection is one of the most frequent bacterial causes of human enteritis in the United States and may be the most commonly identified bacterial cause of acute gastroenteritis worldwide.

Etiology.

Campylobacter organisms are thin, curved, gram-negative, non–spore-forming rods that usually have tapered ends; they can be short and S-shaped or long, multispiraled, and filamentous. In older cultures, coccal forms may be seen. The organisms are motile, with a flagellum at one or both poles and form small (0.5–1?mm), slightly raised, smooth colonies on solid media. Visible growth in blood culture is often not apparent until 5–14 days after inoculation. Most *Campylobacter* organisms are microaerophilic. They neither oxidize nor ferment carbohydrates. Selective culture media developed to enhance isolation of *C. jejuni* may not support, and could even inhibit, the growth of other *Campylobacter* species. *C. jejuni* has a circular chromosome of 1.64 million base pairs (30.6% G + C). This is predicted to encode 1,654 proteins and 54 stable RNA species. The genome is unusual in that there are virtually no insertion sequences of phage-associated sequences and very few repeat sequences.

Clinical presentations associated with *Campylobacter* differ, in part, by species (Table 185–1). Intestinal disease is usually associated with *C. jejuni* and *C. coli*, and extraintestinal and systemic infections are usually associated with *C. fetus*. However, *C. jejuni* septicemia is increasingly recognized; this at times occurs without signs. Less frequently, enteritis is recognized in association with isolation of *C. lari, C. fetus*, and other species.

Epidemiology.

Human campylobacterioses most commonly result from ingestion of contaminated food or water, from direct contact with environmental sources (i.e., a pet), or from person-to-person transmission.

Campylobacter organisms are global in distribution and are ubiquitous in the environment. Although chickens are the classic source of *Campylobacter*, essentially all animal sources of food for humans have been shown to harbor or can harbor *Campylobacter*. Oysters and mussels have recently been shown to harbor these organisms. Additionally, many animals kept as human pets can carry *Campylobacter*. Puppies with diarrhea have been associated with human illness. Beetles and flies that frequent chicken farms may harbor *C. jejuni*. Direct or indirect exposure to this plethora of environmental sources is the primary route by which humans get infection.

Direct transmission of *Campylobacter* between humans is possible. *C. jejuni* and *C. coli* may spread person-to-person, perinatally, and where diapered toddlers are present. Individuals infected with *C. jejuni* usually shed the organism for weeks but may shed for months. The minimum human infectious dose for *C. jejuni* is a few hundred colony-forming units in some volunteers; however, very large inocula fail to make some individuals sick. The infectious dose for other species is unknown.

TABLE 185-1 -- ***Campylobacter* Species Associated with Human Disease**

Species	Clinical Illnesses in Humans	Common Sources
C. jejuni	Gastroenteritis, bacteremia	Poultry, raw milk, cats, dogs, cattle, swine, monkeys, water
C. coli	Gastroenteritis, bacteremia	Poultry, raw milk, cats, dogs, cattle, swine, monkeys, oysters, water
C. fetus	Bacteremia, meningitis, endocarditis, mycotic aneurysm, diarrhea, relapsing fevers, abortions	Sheep, cattle, birds
C. hyointestinalis	Diarrhea, bacteremia, proctitis	Swine, cattle, deer, raw milk, oysters
C. lari	Diarrhea, colitis, appendicitis, bacteremia, urinary tract infection	Seagulls, water, poultry, cattle, oysters, mussels
C. upsaliensis	Diarrhea, bacteremia, abscesses, enteritis, colitis, hemolyticuremic syndrome, abortion	Cats, other domestic pets

C. concisus	Diarrhea, gastritis, enteritis, periodontitis	
C. sputorum	Diarrhea, bedsores, abscesses, periodontitis	Swine
C. rectus	Periodontitis	
C. mucosalis	Enteritis	Swine
C. jejuni subspecies doylei	Diarrhea, colitis, appendicitis, bacteremia, urinary tract infection	
C. curvus	Gingivitis	Poultry, raw milk, cats, dogs, cattle, swine, monkeys, water
C. gracilis	Abscesses (head and neck, abdominal, empyema)	
C. cryaerophila	Diarrhea	Swine

Pathogenesis.

Widely disparate pathology results from infections with *Campylobacter*. Evidence from the well-studied species *C. jejuni* suggests that most infections do not cause symptoms. The frequency of asymptomatic infections with other *Campylobacter* species is less well known.

When disease follows *Campylobacter* colonization, the pathology generally reflects the site at which the bacteria localize, whether or not septicemia occurs, and whether immunoreactive complications are triggered. Species of *Campylobacter* differ markedly in preferred sites of colonization and propensity to cause bacteremia.

Some studies suggest that in vitro invasion of cultured cells corresponds to isolates from patients with colitis, but others have failed to show relationships between in vitro invasion and clinical disease. A cholera-like enterotoxin that causes fluid accumulation in intestinal loop assays and fluid secretion into intestines in an animal model has been described. This enterotoxin can be detected with ganglioside GM_1 -based enzyme-linked immunosorbent assay. *Campylobacter* exhibits various cytotoxic activities (including cytolethal distending toxin, Shiga-like toxin, and hemolysin). Because the inflammatory pathology in some *Campylobacter* infections is consistent with cytotoxins, a role for these in human disease is postulated. As with the enterotoxin, direct evidence of a role for cytotoxins in human disease is not available.

C. fetus possesses a high molecular weight S-layer protein that endows this species with high-level resistance to serum-mediated killing and phagocytosis and is thus thought to be responsible for its propensity to bacteremia. *C. jejuni* and *C. coli* isolates are mostly sensitive to serum-mediated killing, but variants of greater resistance exist. It has been suggested that these serum-killing–resistant variants may be more capable of systemic dissemination.

There is a strong association between Guillain-Barré syndrome and preceding infection with some serotypes of *C. jejuni*. The core oligosaccharides of the lipopolysaccharide of the neuropathic serotypes contain tetrasaccharides or pentasaccharides identical with those of several gangliosides including GM_1 , GD_{1a} , and GQ_{1b} . Molecular mimicry between nerve tissue and this group of infectious agents may be the triggering factor in *Campylobacter*-associated Guillain-Barré syndrome and Miller-Fisher syndrome, a variant of Guillain-Barré syndrome characterized by ataxia, areflexia, and ophthalmoplegia.

Clinical Manifestations.

There are several clinical presentations of *Campylobacter* infections that link to the species involved and host factors, such as age, immunocompetence, and underlying conditions. The most common presentation is acute enteritis.

ACUTE GASTROENTERITIS.

Diarrhea is usually caused by *C. jejuni* (90–95%) or *C. coli* and rarely by *C. lari, C. hyointestinalis*, or *C. upsaliensis*. The incubation period is 1–7 days. Patients may have loose, watery stools or bloody and mucus-containing stools (dysentery). Blood appears in the stools 2–4 days after the onset of symptoms. Fever, vomiting, malaise, and myalgia are common. Fever may be the only initial manifestation, but 60–90% of older children also complain of abdominal pain. The abdominal pain is periumbilical; cramping may precede other symptoms or persist after the stools return to normal. Abdominal pain may mimic appendicitis or intussusception.

Mild infection lasts only 1–2 days and resembles viral gastroenteritis. Most patients recover in less than 1 wk, although 20–30% remain ill for 2 wk and 5–10% longer. Persistent or recurrent *Campylobacter* gastroenteritis and emergence of erythromycin resistance during therapy have been reported in immunocompetent persons, patients with hypogammaglobulinemia (congenital or acquired), and patients with AIDS. Persistent infection may mimic chronic inflammatory bowel disease. Fecal shedding of the organisms in untreated patients usually lasts for 2–3 wk. The range may be from a few days to several months. Young children tend to shed the organisms for longer periods. Acute appendicitis, mesenteric lymphadenitis, and ileocolitis have been reported in patients who have had appendectomies during *C. jejuni* infection.

BACTEREMIA.

Campylobacter bacteremia most often occurs in malnourished children, in patients with chronic illnesses, in those with immunodeficiency, and at the extremes of age. *C. fetus* may cause bacteremia in adults with or without identifiable focal infection. Most have underlying conditions such as malignancy or diabetes mellitus. Bacteremia, when symptomatic, is associated with fever, headache, and malaise. Relapsing or intermittent fever is associated with night sweats, chills, and weight loss when the illness is prolonged. Lethargy and confusion can occur, but focal neurologic signs are unusual without cerebrovascular disease or meningitis. Abdominal pain is frequent; diarrhea, jaundice, and hepatomegaly are less common. A cough may

occur, but pulmonary parenchymal involvement is unusual. Results of the physical examination are unimpressive except for the ill appearance of the patient. Moderate leukocytosis may be found. Both transient asymptomatic bacteremia and rapidly fatal septicemia have been described. A prolonged bacteremia of 8–13 wk has been described, with spontaneous remissions and relapses, especially in immunocompromised hosts. In HIV-infected patients, bacteremia is more frequent with increased morbidity and mortality. Occasional reports describe bacteremia with *C. upsaliensis*.

FOCAL EXTRAINTESTINAL INFECTIONS.

Focal infections caused by *C. jejuni* occur mainly in neonates or immunocompromised

patients. These include meningitis, pancreatitis, cholecystitis, ileocecitis with right lower quadrant pain mimicking appendicitis, urinary tract infection, arthritis, and peritonitis. *C. fetus* shows a predilection for vascular endothelium, causing endocarditis, pericarditis, thrombophlebitis, and mycotic aneurysms; focal infections include meningitis, septic arthritis, osteomyelitis, urinary tract infections, lung abscess, and cholangitis. *C. hyointestinalis* has been associated with proctitis, *C. upsaliensis* with breast abscesses, and *C. rectus* with periodontitis.

PERINATAL INFECTIONS.

Severe perinatal infections, although uncommon, are usually caused by *C. fetus* and, rarely, by *C. jejuni*. Maternal *C. fetus* and *C. jejuni* infections, which may be asymptomatic, may result in abortion, stillbirth, premature delivery, or neonatal infection with sepsis and meningitis. Newborn infection with *C. jejuni* is associated with diarrhea that may be bloody; *C. fetus* rarely causes diarrhea.

Diagnosis.

The clinical presentation of *Campylobacter* enteritis is similar to that of enteritis caused by other bacterial enteropathogens. The differential diagnosis should include *Shigella, Salmonella*, invasive *Escherichia coli, E. coli* O157:H7, *Yersinia enterocolitica, Aeromonas, Vibrio parahaemolyticus*, and amebiasis. Fecal leukocytes are found in as many as 75% of cases and fecal blood in 50%.

The diagnosis of *Campylobacter* is usually confirmed by identification of the organism in culture. Selective media, such as Skirrow or Butzler media, and microaerophilic conditions (5–10% oxygen) are commonly used. Some *C. jejuni* grow best at 42°C. Filtration methods are available and can preferentially enrich for *Campylobacter* by selecting for their smaller size. These methods allow for subsequent culture of the enriched sample on antibiotic free media. This enhances rates of isolation of those *Campylobacter* inhibited by the antibiotics included in standard selective media.

For rapid diagnosis of *Campylobacter* enteritis, direct carbolfuchsin stain of fecal smear, indirect fluorescence antibody test, dark-field microscopy, or latex agglutination can be used. Antigen detection by enzyme immunoassay is nearly as sensitive and specific as culture. Species-specific DNA probes and specific gene amplification by polymerase chain reaction have been described, although clinical experience is limited. Serologic diagnoses may be made with enzyme-linked immunoassays to measure the antibody (IgG, IgM, IgA) levels to *C. jejuni* for epidemiologic investigations.

Treatment.

Fluid replacement, correction of electrolyte imbalance, and supportive care are the mainstays of treatment of children with *Campylobacter* gastroenteritis. Antimotility agents may cause prolonged or fatal disease and should not be used.

The need for antibiotic therapy in patients with uncomplicated gastroenteritis is controversial. Some data suggest a shortened duration of symptoms and intestinal shedding if erythromycin ethylsuccinate suspension is initiated early in the disease in patients with the dysenteric form of *Campylobacter* enteritis.

Most *Campylobacter* are susceptible to macrolides, aminoglycosides, chloramphenicol, imipenem, and clindamycin and are resistant to cephalosporins, tetracyclines, rifampin, penicillins, trimethoprim, and vancomycin. Quinolone resistance has developed recently and has been related to the use of quinolones in veterinary medicine. Erythromycin-resistant *Campylobacter* isolates remain uncommon and erythromycin is still the drug of choice if therapy is required. Clarithromycin and azithromycin show good in vitro activity, but clinical evaluation is limited. Antibiotics are recommended for patients with the dysenteric form of the disease, high fever, or a severe course and for children who are immunosuppressed or have underlying diseases.

Extraintestinal infection caused by *Campylobacter* requires parenteral antibiotic therapy with an aminoglycoside, imipenem, or both. In patients with *C. fetus* bacteremia, prolonged therapy is advised. *C. fetus* isolates resistant to erythromycin have been reported.

Complications.

Severe, prolonged *C. jejuni* infection can occur in patients with immunodeficiencies including hypogammaglobulinemia and malnutrition. In patients with AIDS, an increased frequency and severity of *C. jejuni* infection have been reported; severity correlates inversely with CD4 count.

REACTIVE ARTHRITIS.

Reactive arthritis may accompany *Campylobacter* enteritis in adolescents and adults, especially those who are positive for HLA-B27. It appears 5–40 days after the onset of diarrhea, involves mainly large joints, and resolves without any sequelae. The arthritis typically is migratory, but the child is afebrile. Synovial fluid is always sterile.

Reiter syndrome (i.e., reactive arthritis with conjunctivitis, urethritis, and rash) and erythema nodosum are less common. IgA nephropathy and immune complex glomerulonephritis with *C. jejuni* antigens in the kidneys have been reported. Other complications are hemolytic anemia and rectal bleeding.

GUILLAIN-BARRÉ SYNDROME.

Guillain-Barré syndrome is an acute demyelinating disease of the peripheral nervous system characterized clinically by acute flaccid paralysis. *C. jejuni* is an important causal factor for GBS. GBS has been reported 1–12 wk after culture-proven *C. jejuni* gastroenteritis. Stool cultures obtained from patients with Guillain-Barré syndrome at the onset of neurologic symptoms have yielded *C. jejuni* in more than 25% of the cases. Serologic studies suggest that 20–45% of patients with Guillain-Barré syndrome have evidence of recent *C. jejuni* infection. The management of Guillain-Barré syndrome includes supportive care, plasma exchange, and intravenous immunoglobulin (Chapter 607).

Prognosis.

Although *Campylobacter* gastroenteritis is usually self-limited, immunosuppressed children, including those with AIDS, may experience a protracted or a severe course. Septicemia in newborns and immunocompromised hosts has a poor prognosis, with an estimated mortality rate of 30–40%.

Prevention.

Most human campylobacterioses are acquired indirectly or directly from infected animals. Interventions to minimize transmission include preparing food under conditions that kill *Campylobacter* and that prevent recontamination after cooking (not using the same surfaces, utensils, or containers for both uncooked and cooked food), ensuring that water sources are not contaminated and that water is kept in clean containers, and taking steps to prevent direct transmission from infected persons or infected domestic pets. Breast-feeding appears to decrease symptomatic *Campylobacter* disease but does not reduce colonization.

Several approaches at immunization are being studied, including the use of live-attenuated organisms, subunit vaccines, and killed whole cell vaccines. A candidate whole cell vaccine in combination with an oral adjuvant is in clinical trials.

Chapter 186 - *Yersinia*

James R. Murphy
Gloria P. Heresi

The genus *Yersinia* comprises more than 10 named species, three of which are clearly pathogens of humans. *Yersinia enterocolitica*, by far the most frequent *Yersinia* causing human disease, produces fever, abdominal pain, and diarrhea that may mimic appendicitis. *Yersinia pseudotuberculosis* may cause a similar clinical presentation. *Yersinia pestis*, the agent of plague, most commonly causes an acute febrile lymphadenitis (bubonic plague) and less frequently presents as septicemic, pneumonic, or meningeal plague. Untreated plague carries a significant mortality rate. Other *Yersinia* are infrequent causes of infections of humans and their identification is often an indicator of immune deficit. *Yersinia* is a zoonotic and can be found in most areas of the world. The organisms can colonize domestic pets. Infection of humans most often results from contact with infected animals or their tissues, ingestion of contaminated water, milk, or meat or, for *Y. pestis*, the bite of infected fleas.

186.1 *Yersinia enterocolitica*

Etiology.

Y. enterocolitica is a large, gram-negative coccobacillus that exhibits little or no bipolarity when stained with methylene blue and carbolfuchsin. These facultative anaerobes grow well on commonly available culture media and are motile at 22°C but not at 37°C. *Y. enterocolitica* comprises pathogenic and nonpathogenic members.

Epidemiology.

Y. enterocolitica is transmitted to humans through food, water, animal contact, and contaminated blood products. Transmission can occur from mother to newborn. *Y. enterocolitica* appears to have a global distribution but is seldom a cause of tropical diarrhea. There is approximately one culture-proved *Y. enterocolitica* infection per 100,000 population/yr in the United States, but infection may be more frequent in northern Europe. Cases are more frequent in colder months, younger individuals, and males. Most infections in children are in patients <7 yr of age, with the majority of infections in children <1 yr of age.

Natural reservoirs of *Y. enterocolitica* include rodents, rabbits, pigs, sheep, cattle, horses, dogs, and cats. Contact with feral animals or colonized pets is the common source of human infections. Culture and molecular techniques have found the organism in a variety of foods and in water. A major contamination source of sporadic *Y. enterocolitica* infections is edible pig offal (chitterlings). In one study, 71% of human isolates were indistinguishable from the strains isolated from tongues, livers, kidneys, and hearts of pigs, confirming that contaminated pig offal is an important vehicle in the transmission of *Y. enterocolitica* from slaughterhouses to humans. *Y. enterocolitica* has been demonstrated as an occupational threat to butchers.

Over recent decades, *Y. enterocolitica* infections have increased while *Y. pseudotuberculosis* infections have declined, leading to the suggestion that the former organism is replacing the latter in an ecologic niche. In part, the mass production of animals, development of meat factories based on sophisticated chains of cold storage, and international trade of meat products and animals are believed to be the reasons for the increasing prevalence of yersiniosis in humans. *Y. enterocolitica* can proliferate at refrigerator temperatures.

Pathogenesis.

The organisms most often enter by the alimentary tract and cause mucosal ulcerations in the ileum. Necrotic lesions of Peyer patches and mesenteric lymphadenitis occur. If septicemia develops, suppurative lesions can be found in infected organs. Infection may trigger reactive arthritis and erythema nodosum.

Adherence, invasion, and toxin production are established as essential mechanisms of pathogenesis. Recently, it was demonstrated that bacterial components, some associated with the bacterial type III secretion apparatus, can actively suppress immunologic capacities, suggesting that immunosuppression may contribute to pathogenesis. Motility appears to be required for *Y. enterocolitica* pathogenesis. Serogroups that predominate in human illness are 0:3, 0:8, 0:9, and 0:5,27. Virulence traits are both chromosomal and plasmid encoded. Possibly because pathogenic strains require iron, individuals with iron overload like hemochromatosis, thalassemia, and sickle cell disease are at high risk of infection.

Clinical Manifestations.

Disease presents most often as enterocolitis with diarrhea, fever, and abdominal pain. Acute enteritis is more common among younger children, and mesenteric lymphadenitis that may mimic appendicitis may be found in older children and adolescents. *Y. enterocolitica* septicemia is less common and most often found in very young children (<3 mo of age) and in individuals with underlying immune-compromising conditions. Systemic infection has been associated with splenic and hepatic abscesses, osteomyelitis, meningitis, endocarditis, and mycotic aneurysms. Exudative pharyngitis, pneumonia, empyema, lung abscess, and acute respiratory distress syndrome may infrequently occur.

Reactive complications include erythema nodosum and polyarthritis. These may be

more frequent in selected populations (northern Europeans) and in association with HLA-B27 and are more frequent in females.

Stools may be watery or contain leukocytes and less frequently frank blood and mucus. *Y. enterocolitica* is excreted in stool for 1–4 wk. Family contacts of a case may frequently be found to be asymptomatically colonized with *Y. enterocolitica*.

Diagnosis.

Culture of *Y. enterocolitica* is the primary method of diagnosis. The organism is easily cultured from normally sterile sites but requires special procedures for isolation from stool where other bacteria may outgrow *Y. enterocolitica*. Many laboratories do not routinely perform the procedures required to isolate *Y. enterocolitica* and cultures targeted to this organism must be specifically requested. A history indicating contact with environmental sources of *Yersinia* and detection of fecal leukocytes are helpful indicators of a need to culture for *Y. enterocolitica*. The culture isolation of a *Yersinia* from stool should be followed by tests to confirm that the isolate is a pathogen.

DIFFERENTIAL DIAGNOSIS.

Clinical presentation is similar to other bacterial causes of enterocolitis. The most common differential is among *Shigella, Salmonella, Campylobacter, Clostridium difficile*, enteroinvasive *Escherichia coli*, and inflammatory bowel disease.

Treatment.

Enterocolitis occurring in an immunocompetent individual is a self-limiting disease and no benefit to antibiotic therapy is established. Patients with systemic infection and very young children in whom septicemia is common should be treated. Many *Yersinia* strains are sensitive to trimethoprim-sulfamethoxazole (TMP-SMZ), aminoglycosides, third-generation cephalosporins, and quinolones. TMP-SMZ is recommended as empirical treatment in children because most strains are sensitive and it is well tolerated by children. In more severe infection such as bacteremia, third-generation cephalosporins with or without aminoglycosides have been shown effective. *Y. enterocolitica* produces

ß-lactamases a and b responsible for resistance to penicillins and cephalosporins. Patients on deferoxamine should discontinue iron chelation therapy during treatment for *Y. enterocolitica,* especially if they have complicated gastrointestinal infection or extraintestinal infection.

Complications.

Reactive arthritis, erythema nodosum, erythema multiforme, hemolytic anemia, thrombocytopenia, and systemic dissemination of bacteria have been reported in association with *Y. enterocolitica* infection. Septicemia is more frequent in younger children and reactive arthritis in older patients. Arthritis seems mediated by immune complexes and viable organisms are not present in involved joints.

Prevention.

Prevention centers on reducing contact with environmental sources of *Yersinia*. Breaking or sterilization of the chain from animal reservoirs to humans holds the greatest potential to reduce infections and the techniques applied must be tailored to the reservoirs in each area. There is no vaccine available.

186.2 *Yersinia pseudotuberculosis*

Y. pseudotuberculosis is so named because it causes tuberculosis-like lesions in guinea pigs. The agent has a worldwide distribution but *Y. pseudotuberculosis* disease is less frequent than *Y. enterocolitica* disease. The most common form of disease is a mesenteric lymphadenitis that produces an appendicitis-like syndrome. *Y. pseudotuberculosis* also causes a Kawasaki syndrome–like illness.

Etiology.

Y. pseudotuberculosis is differentiated biochemically from *Y. enterocolitica* on the basis of ornithine decarboxylase activity, fermentation of sucrose, sorbitol, cellobiose, and other tests, although some overlap between species may be noted. Antisera to somatic O antigens and sensitivity to *Yersinia* phages may also be used to differentiate the two species. Subspecies-specific DNA sequences that allow direct probe- and primer-specific differentiation of *Y. pestis, Y. pseudotuberculosis*, and *Y. enterocolitica* have been described. *Y. pseudotuberculosis* is more closely related to *Y. pestis* than to *Y. enterocolitica*.

Epidemiology.

Yersinioses are zoonotic infections with reservoirs in wild rodents, rabbits, deer, farm animals, various birds, and domestic animals including cats and canaries. Transmission to humans is by consumption of contaminated animals, contact with these animals, or contact with an environmental source, often water, contaminated by these animals. Infections are more commonly reported from Europe, in males, and in the winter.

Pathogenesis.

Ileal and colonic mucosal ulceration and mesenteric lymphadenitis are hallmarks of the infection. Necrotizing epithelioid granulomas may be seen in the mesenteric lymph nodes, but the appendix is frequently grossly and microscopically normal. The mesenteric nodes are often the only source of isolation of the organisms. *Y. pseudotuberculosis* antigens bind directly to HLA class II molecules and may function as superantigens, which may account for the clinical illness resembling Kawasaki syndrome caused by this organism.

Clinical Manifestations.

Pseudoappendicitis with abdominal pain, right lower quadrant tenderness, fever, and leukocytosis is the most common clinical presentation. Enterocolitis and extraintestinal spread are uncommon. Age, iron overload, diabetes mellitus, and chronic liver disease are often found concomitantly with extraintestinal *Y. pseudotuberculosis* infection. Renal involvement with tubulointerstitial nephritis, azotemia, pyuria, and glucosuria may occur.

Diagnosis.

Y. pseudotuberculosis is rarely recovered from stool. Involved mesenteric lymph nodes removed at appendectomy may yield the organism by culture. Ultrasound examination of children with unexplained fever and abdominal pain may reveal a characteristic picture of enlarged mesenteric lymph nodes, thickening of the terminal ileum, and no image of the appendix.

DIFFERENTIAL DIAGNOSIS.

Appendicitis (most commonly), inflammatory bowel disease, and other intra-abdominal infections should be considered. Kawasaki syndrome, staphylococcal or streptococcal disease, leptospirosis, Stevens-Johnson syndrome, and collagen vascular diseases including acute-onset juvenile rheumatoid arthritis can mimic the syndrome with prolonged fever and rash.

Treatment.

Uncomplicated mesenteric lymphadenitis due to *Y. pseudotuberculosis* is a self-limited disease, and antimicrobial therapy is not required. Culture-confirmed bacteremia should be treated with an aminoglycoside, ampicillin, chloramphenicol, or a third-generation cephalosporin.

Complications.

An illness with presentation similar to Kawasaki disease may occur. There may be fever of 1–2 days' duration, strawberry tongue, pharyngeal erythema, a scarlatiniform rash, cracked red swollen lips, conjunctivitis, sterile pyuria, periungual desquamation, and thrombocytosis. Coronary aneurysm has been described. Erythema nodosum and arthritis may follow infection.

Prevention.

The sporadic nature of the disease makes application of targeted prevention measures difficult. Avoiding exposure to potentially infected animals and good food handling practices could prevent infection.

186.3 Plague (*Yersinia pestis*)

Etiology.

Y. pestis is a gram-negative coccobacillus belonging to the Enterobacteriaceae. The bacterium has several chromosomal and plasmid-associated factors that are essential to its virulence and survival in mammalian hosts and fleas. The nonmotile bacterium was first isolated by Yersin in 1894 and shares bipolar staining appearance with *Y. pseudotuberculosis. Y. pestis* can be differentiated from *Y. pseudotuberculosis* by biochemical reactions, serology, selected *Yersinia* phage sensitivity, and selected molecular techniques. The genome of *Y. pestis* is published.

Epidemiology.

Plague is endemic in at least 24 countries. In the United States, plague is most common west of a line from east Texas to east Montana. The epidemic form of disease killed about one fourth of the population of Europe in the Middle Ages. Plague is infrequent in the United States (0–40 reported cases per year) with 80% of cases in the southwestern states of New Mexico, Arizona, and Colorado. Transmission to humans is most commonly from wild animal sources, although most cases of inhalation plague reported recently to the Centers for Disease Control and Prevention (CDC) were associated with exposure to infected free-roaming domestic cats.

The most common mode of transmission of *Y. pestis* to humans is by the bite of infected fleas, and historically most human infections are thought to have resulted from bites of fleas that acquired infection from feeding on infected urban rats. Less frequently, infection is caused by contact with infectious body fluids or tissues or inhaling infectious droplets. Sylvatic plague may exist as a stable enzootic infection or as an epizootic disease with high host mortality. Ground squirrels, rock squirrels, prairie dogs, rats, mice, bobcats, cats, rabbits, and chipmunks may be infected. Transmission among animals is usually by flea bite or by ingestion of contaminated tissue.

The lack of nucleotide diversity in the *Y. pestis* genome supports the view that *Y. pestis* has emerged relatively recently in evolutionary history from the closely related gastrointestinal pathogen *Y. pseudotuberculosis* (probably serotype 0:1b).

Pathogenesis.

Infected fleas regurgitate organisms into a patient's skin during feeding attempts. The bacteria appear to migrate via cutaneous lymphatics to the regional lymph nodes where *Y. pestis* replicates, resulting in **bubonic plague**. In the absence of specific therapy, bacteremia may occur, resulting in purulent, necrotic, and hemorrhagic lesions in many organs. Both plasmid and chromosomal genes are required for full virulence.

Pneumonic plague occurs when infected material is inhaled. The organism is highly

transmissible from persons with pneumonic plague and from domestic cats with pneumonic infection. This high transmissibility and high morbidity and mortality have provided an impetus for attempts to use *Y. pestis* as a biological weapon (Chapter 706).

Clinical Manifistations.

Y. pestis infection can present as several clinical syndromes and infection may be subclinical. The three principal clinical presentations of plague are bubonic, septicemic, and pneumonic. Bubonic plague is the most frequent form (80–90% of cases in the United States). From 2–8 days after a flea bite, a 1–10?cm lymph nodes, or **bubo**, which is remarkable for its tenderness, develops in a draining lymph node located in the inguinal (most common), axillary, or cervical region depending on the inoculation site. Fever, chills, weakness, prostration, headache, and the development of septicemia are common. The skin may show insect bites or scratch marks. Purpura and gangrene of the extremities may develop as a result of disseminated intravascular coagulation. These lesions may be the origin of the name **Black Death**. Untreated plague can kill up to 50% of symptomatic individuals and death may occur within 2–4 days after onset of symptoms.

Occasionally, *Y. pestis* may establish systemic infection and induce the systemic symptoms seen with bubonic plague without causing a bubo (**primary septicemic plague**). Because of the delay in diagnosis linked to the lack of the bubo, septicemic plague carries a higher case fatality rate than bubonic plague. In some regions, bubo-free septicemic plague may comprise one fourth of cases.

Pneumonic plague is the least common but most dangerous and fatal form of the disease. Pneumonic plague may result from hematogenous dissemination, or rarely as **primary pneumonic plague** after inhalation of the organism from a human or animal with plague pneumonia or potentially from a biologic attack. Signs of pneumonic plague include severe pneumonia with high fever, dyspnea, and hemoptysis.

Plague meningitis, tonsillitis, or gastroenteritis may occur. Meningitis tends toward a late complication following inadequate treatment. Tonsillitis and gastroenteritis may occur with or without apparent bubo formation or lymphadenopathy.

Diagnosis.

A febrile patient who has been exposed to small animals in endemic areas should be suspected of having plague. Thus, bubonic plague is suspected in a patient with a painful swollen lymph node, fever, and prostration who has been exposed to fleas or rodents in the western United States. A history of camping or the presence of flea bites should increase the index of suspicion. Laboratory diagnosis is based on bacteriologic culture or direct visualization using Gram, Giemsa, or Wayson stains of lymph node aspirates, blood, sputum, or exudates. *Y. pestis* grows well under routine culture conditions. Suspected isolates of *Y. pestis* should be forwarded using special containment precautions to a reference laboratory for confirmation. Cases of plague should be reported immediately to local and state health departments and the CDC.

DIFFERENTIAL DIAGNOSIS.

Gram stain of *Y. pestis* may be confused with that of *Enterobacter agglomerans*. Mild and subacute forms of bubonic plague may be confused with other disorders causing localized lymphadenitis and lymphadenopathy. Septicemic plague may be indistinguishable from other forms of overwhelming bacterial sepsis.

Treatment.

Patients suspected of having bubonic plague should be placed on isolation until 2 days after starting antibiotic treatment to prevent the potential spread of the disease if the patient develops pneumonia. The treatment of choice for bubonic plague has been streptomycin (30?mg/kg/24?hr divided q 12?hr IM for 10 days). However, intramuscular streptomycin is inappropriate for septicemia because absorption from muscles may be erratic when perfusion is poor. The poor central nervous system penetration of streptomycin makes this an inappropriate drug for meningitis. Septicemia and meningitis are usually treated with chloramphenicol (60–100?mg/kg/24?hr divided q 6?hr IV). Resistance to these agents and relapses are rare. *Y. pestis* is susceptible to penicillin in vitro but this is ineffective in treatment of human disease. Mild disease may be treated with oral chloramphenicol or tetracycline in children >9 yr of age. Prophylaxis or expectant treatment should be given to close contacts of patients with pneumonic plague. Recommended regimens include a 7-day course of tetracycline, doxycycline, or trimethoprim-sulfamethoxazole. Contacts of cases of uncomplicated bubonic plague do not require prophylaxis.

Prevention.

Avoidance of exposure to infected animals and fleas is the best method of prevention of infection. Patients with plague should be isolated if they have pulmonary symptoms, and infected materials should be handled with extreme care. A vaccine is available for individuals at high risk of infection.

Chapter 187 - *Aeromonas* and *Plesiomonas*

James R. Murphy
Gloria P. Heresi

Aeromonas and *Plesiomonas* organisms cause enteritis and less frequently skin and soft tissue infections and septicemia. These organisms are common in fresh and brackish water and in and on animals and plants in contact with water.

187.1 *Aeromonas*

Etiology.

Aeromonas are members of the Vibrionaceae family. They are oxidase-positive, facultatively anaerobic, gram-negative bacilli. The species most often associated with human infection are *A. hydrophila*, *A. veronii* biotype *sobria*, and *A. caviae*.

Aeromonas infect a wide variety of warm- and cold-blooded animals. In humans, infection with *Aeromonas* is associated with three distinct syndromes: gastroenteritis, skin and soft tissue infections, and septicemia. *Aeromonas* strains are divided into two major groups: the nonmotile psychrophilic organisms that infect cold-blooded animals and the motile mesophilic organisms that infect humans and other warm-blooded animals.

Epidemiology.

Aeromonas organisms are ubiquitous. They are present in numerous environmental fresh and brackish aquatic sources including rivers and streams, well water, and sewage. They are most often cultivated from aquatic sources during warm weather months. However, prevalence of human infection may or may not exhibit seasonality, apparently depending on local conditions. *Aeromonas* organisms have been isolated from meats, milk, and vegetables consumed as human food. Most human infections are associated with exposure to contaminated water. Asymptomatic colonization with *Aeromonas* occurs in humans and is more common in inhabitants of tropical regions.

Pathogenesis.

Clinical and epidemiologic data demonstrate that many *Aeromonas* are enteric pathogens. However, adult volunteers fed 10^4 –10^{10} colony-forming units of *Aeromonas* did not develop diarrhea or become colonized. *Aeromonas* possesses various potential virulence factors including a- and ß-hemolysin, adherence fimbriae, enterotoxin, protease, and chitinase. The ß-hemolysin has been shown to be cytotoxic to various cell lines. Enterotoxin causes fluid accumulation in rabbit ileal loops, increases intracellular cyclic adenosine monophosphate in rabbit intestinal epithelium, and cross reacts immunologically with cholera toxin. The protease may have a role in extraintestinal manifestations of *Aeromonas* infections. A few strains produce shiga toxin. It is not clear which of the potential virulence traits define strains that cause illness. Normal human serum generally promotes phagocytosis and intracellular killing of *Aeromonas* and the lack of this serum action has been linked to poor prognosis.

Clinical Manifestations.

Colonization with *Aeromonas* may be asymptomatic or cause illness, including gastroenteritis, focal invasive infection, and septicemia. Apparently immunologically normal individuals may present with each manifestation, but invasive disease is more commonly seen in immunologically compromised individuals.

ENTERITIS.

The most common clinical manifestation of infection with *Aeromonas* is enteritis. This occurs primarily in children <3 yr old. Studies suggest that, in some locations, it is the third or fourth most common cause of childhood bacterial diarrhea. *Aeromonas* have been isolated from 2–10% of patients with diarrhea and 1–5% of asymptomatic control subjects in various studies. The diarrheal illness is often watery and self-limited, although a dysentery-like syndrome with blood and mucus in the stool has also been described. Fever and vomiting are common in children. Gastroenteritis caused by *A. hydrophila* and *A. sobria* tends to be acute and self-limited, whereas one third of the patients with *A. caviae* gastroenteritis have chronic or intermittent diarrhea that may last 4–6 wk. Complications of *Aeromonas* gastroenteritis include intussusception, failure to thrive, hemolytic-uremic syndrome, bacteremia, and strangulated intestinal hernia.

SKIN AND SOFT TISSUE INFECTION.

A. hydrophila is the predominant species associated with skin and soft tissue infections, with peak incidence during the summer months. Skin and soft tissue infection is the second most common presentation of *Aeromonas* infection. Predisposing factors include local trauma and exposure to contaminated fresh water. *Aeromonas* soft tissue infections have been reported to result from alligator bites, water-sport injuries, tick bites, and the use of medicinal leech therapy. The spectrum of skin and soft tissue infections is broad, ranging from a localized skin nodule to life-threatening necrotizing fasciitis and myonecrosis. *Aeromonas* cellulitis is indistinguishable from that due to other bacterial pathogens that cause cellulitis but should be suspected in wounds in contact with a water source, especially during the summer.

SEPTICEMIA.

Aeromonas septicemia, the third most frequent presentation of infection with *Aeromonas*, is associated with a high mortality rate (reported range 27–73%). *Aeromonas* septicemia usually occurs in patients with underlying conditions such as hepatobiliary disease or malignancy but may occur in an immunocompetent host. *Aeromonas* may be the only organism isolated or may be part of a polymicrobial bacteremic syndrome. *A. hydrophila* septicemia tends to occur in patients with less serious underlying disease. *A. caviae* tends to associate with polymicrobial septicemia and is isolated more often from patients with underlying illnesses.

OTHER INFECTIONS.

Aeromonas is a rare cause of necrotizing gastroenteritis, endocarditis, meningitis, osteomyelitis, pyogenic arthritis, endophthalmitis, urinary tract infection, peritonitis, myositis, cellulitis, necrotizing fasciitis, cholecystitis, lung abscess, and pneumonia. *Aeromonas* can be associated with aspiration pneumonia after a near-drowning event.

Diagnosis.

Diagnosis is by culture isolation of *Aeromonas*. The organism is easily grown on standard media when the source material is normally sterile. However, isolation of the organism from samples containing numerous bacteria is more difficult, presumably because competing bacteria outgrow *Aeromonas*. Use of selective media such as a blood agar supplemented with ampicillin or MacConkey agar containing Tween 80 and ampicillin enhances isolation. Most (~90%) strains produce ß-hemolysis on blood agar. Lactose-fermenting strains of *Aeromonas* may be overlooked in stool specimens if the clinical laboratory does not routinely perform oxidase tests on lactose fermenters isolated on MacConkey or does not routinely use selective media for the isolation of *Aeromonas*.

Treatment.

Aeromonas gastroenteritis is usually self-limited, and antimicrobial therapy may not be indicated. No controlled trials have been carried out; however, data from uncontrolled trials suggest that antimicrobial therapy shortens the course of the illness. Antimicrobial therapy is reasonable to consider in patients with protracted diarrhea, a dysentery-like illness, or underlying conditions such as hepatobiliary disease or immunocompromise. Most isolates are resistant to ampicillin. Septicemia should be treated with an aminoglycoside or a third-generation cephalosporin. Other options include aztreonam, imipenem, chloramphenicol, and trimethoprim-sulfamethoxazole (TMP-SMZ).

187.2 *Plesiomonas shigelloides*

Etiology.

Plesiomonas shigelloides, the only species in the genera, is a fermentative bacilli that is not an Enterobacteriaceae. The organism has been associated with acute gastroenteritis and very rarely extraintestinal infections. *P. shigelloides* is a member of the family Vibrionaceae, although some authorities believe they are related more closely to Enterobacteriaceae. The bacilli are oxidase-positive, facultatively anaerobic, motile, and gram-negative. Analysis of the sequence of 5S rRNA, 16S rRNA, and 16S rDNA suggests that *P. shigelloides* is closely related to Enterobacteriaceae.

Epidemiology.

P. shigelloides is ubiquitous in fresh water and historically has been most often found in warmer and tropical waters. There are increasing reports of isolations in colder regions. *P. shigelloides* colonizes numerous warm- and cold-blooded animals and may cause disease in cats. Infection of humans is thought to be the result of consumption of contaminated water or food and possibly through contact with colonized animals. The role that colonized animals play in the ecology of human infection is poorly understood. Asymptomatic colonization with *S. shigelloides* is common in some tropical and subtropical regions and more infrequent in colder climates. A majority of symptomatic patients seen in North America have either traveled abroad or report exposure to potentially contaminated water or food. Clinical disease in humans begins 24?hr to about 4 days after contact with the organism.

Pathogenesis.

Epidemiologic evidence indicates that *P. shigelloides* is an enteropathogen. However, diarrhea did not develop in volunteers fed *P. shigelloides*. The mechanism of gastroenteritis is not known, but it appears that the species can cause both secretory and invasive disease.

Clinical Manifestations.

Plesiomonas gastroenteritis is usually secretory but occasionally may be dysenteric, with blood and mucus. The frequency of secretory vs dysenteric diarrhea clusters by outbreak report, suggesting that either human populations or bacterial populations associate with type of presentation. Symptoms include fever, headache, abdominal cramping, nausea, vomiting, and diarrhea. Blood, mucus, or both may be passed with stool, and white blood cells may be visualized in stained preparations of stool. The illness usually resolves in about 2 wk, but reports describe diarrhea lasting =4 wk.

Extraintestinal infections are rare and usually occur in patients with underlying conditions such as immunodeficiency, malignancy, sickle cell disease, or cirrhosis. Rarely, bacteremia accompanying gastroenteritis has been documented in apparently otherwise normal children. Extraintestinal disease includes septicemia, meningitis, osteomyelitis, septic arthritis, reactive arthritis, cellulitis, endophthalmitis, pseudoappendicitis, pseudomembranous colitis, proctitis, and cholecystitis. Early onset neonatal sepsis and meningitis are rare but comprise most of reported cases of *P. shigelloides* meningitis; it has a very high mortality rate (80%). Septicemia has a high mortality rate in adults.

Diagnosis.

A history of foreign travel, ingestion of raw seafood, or exposure to contaminated water should raise a suspicion of *P. shigelloides* when clinical presentation matches those described above. Isolation of the organism from stool or sterile body fluids is essential for diagnosis. *P. shigelloides* grows well on traditional enteric media. However, selective techniques may be required to isolate the organism from mixed cultures. It may be under-recognized by clinical laboratories that do not routinely perform an oxidase test. Molecular methodology is under development for diagnostic purposes but is not yet in routine use.

Treatment.

Gastroenteritis due to *P. shigelloides* is usually self-limited. Antimicrobial therapy is reserved for those patients with prolonged or bloody diarrhea. Data from uncontrolled trials suggest that antimicrobial therapy decreases the duration of symptoms. *P. shigelloides* is susceptible to TMP-SMZ, cephalosporins, carbapenems, and quinolones (not approved for use in the United States in children <18 yr of age). *P shigelloides* is commonly resistant to penicillin, streptomycin, and azithromycin.

Antibiotics are essential for therapy of extraintestinal disease. Empirical therapy with a third-generation cephalosporin is reasonable, because most isolates are susceptible in vitro. Definitive therapy should be guided by the susceptibility of the individual isolate.

Chapter 188 - *Pseudomonas*, *Burkholderia*, and *Stenotrophomonas*

Robert S. Baltimore

Pseudomonas and *Burkholderia* live abundantly in soil and water and on plants, and are widespread throughout nature. Most human infections due to these species are opportunistic and occur among low-birthweight infants and in older infants and children with impaired host defenses, such as those with traumatic wounds, cystic fibrosis, malignancies, extensive burns, malnutrition (especially in impoverished populations), and primary immunodeficiencies as well as those receiving immunosuppressive therapy. *Pseudomonas aeruginosa* is an important cause of nosocomial infections including postsurgical infections.

A number of species formerly considered under the genus *Pseudomonas* were reclassified on the basis of rRNA homology. Species formerly classified as *P. cepacia*, *P. mallei*, and *P. pseudomallei* are now *Burkholderia cepacia*, *B. mallei*, and *B. pseudomallei*. *P. maltophilia* is now *Stenotrophomonas maltophilia*.

A large number of *Pseudomonas*, *Burkholderia*, and related organisms have been identified, but only a few are pathogenic for humans; of these, *P. aeruginosa* is by far the most common. Other species occasionally recognized as human pathogens

include *B. cepacia*, *S. maltophilia*, *P. fluorescens*, *B. putrefaciens*, *B. pseudomallei*, and *B. mallei*.

188.1 *Pseudomonas aeruginosa*

P. aeruginosa is a gram-negative rod and is a strict aerobe. It can multiply in most moist environments that contain minimal amounts of organic compounds because it can use any source of carbon. Strains from clinical specimens may produce ß-hemolysis on blood agar; >90% of strains produce a bluish-green phenazine pigment (blue pus) as well as fluorescein, which is yellow-green and fluoresces. These pigments diffuse into and color the medium surrounding the colonies. Strains

of *Pseudomonas* can be differentiated for epidemiologic purposes by serologic, phage, and pyocin typing and by genome restriction fragment length polymorphisms using pulsed-field gel electrophoresis.

Epidemiology.

In a study from Israel the rate of *P. aeruginosa* bacteremia in children was 3.8/1000 patients over 10 yr with a 20% mortality rate, but rates varied according to the prevalent underlying diseases. *P. aeruginosa* and other pseudomonads frequently enter the hospital environment on the clothes, skin, or shoes of patients or hospital personnel, with plants or vegetables brought into the hospital, and in the gastrointestinal tracts of patients. Colonization of any moist or liquid substance may ensue; for example, the organisms may be found growing in distilled water, hospital kitchens and laundries, some antiseptic solutions, and equipment used for respiratory therapy. Colonization of patients' skin, throat, stool, and nasal mucosa is low at admission to the hospital but increases to as high as 50–70% with prolonged hospitalization and the use of broad-spectrum antibiotics, chemotherapy, mechanical ventilation, and urinary catheters. Patients' intestinal microbial flora may be altered by the use of broad-spectrum antibiotics, which reduces resistance to colonization and permits *P. aeruginosa* in the environment to populate the GI tract. Intestinal mucosal breakdown associated with medications, especially cytotoxic agents, and nosocomial enteritis may provide a pathway by which *P. aeruginosa* spreads to the lymphatics or bloodstream.

Pathogenesis.

The requirement of oxygen for growth may account for the lack of invasiveness of *Pseudomonas* after it has colonized or even infected the skin. Invasiveness of *P. aeruginosa* is mediated by a host of virulence factors. It produces endotoxin that is weak compared with that of other gram-negative bacilli. It also produces numerous exotoxins, including exotoxin A, which causes local necrosis and facilitates systemic bacterial invasion, and exoenzyme S, which acts as both an adhesin and a cellular toxin. *Pseudomonas* produces disease in three stages. Bacterial colonization and attachment are facilitated by pili or fimbriae and by opportunistic adhesion to epithelium damaged by prior injury or infection. A mucopolysaccharide may inhibit phagocytosis, whereas extracellular proteins, proteases, elastases, and cytotoxin (formerly leukocidin) digest cell membranes, and antibodies produce capillary vascular permeability and inhibit leukocyte function. Dissemination and bloodstream invasion follow extension of local tissue damage and are facilitated by the antiphagocytic properties of endotoxin, the **mucoid exopolysaccharide**, and protease cleavage of IgG. The host responds to infection by producing antibodies to *Pseudomonas* exotoxin (**exotoxin A**) and lipopolysaccharide. Compromised host defense mechanisms (owing to trauma, neutropenia, mucositis, immunosuppression, impaired mucociliary transport) explain the predominant role of this organism in producing opportunistic infections.

Clinical Manifestations.

Most clinical patterns (Table 188–1) are related to opportunistic infections (Chapter 164) or are associated with shunts and indwelling catheters (Chapter 165). *P. aeruginosa* may be introduced into a minor wound of a healthy person as a secondary invader, and cellulitis and a localized abscess that exudes green or blue pus may follow. The characteristic skin lesions of *Pseudomonas*, **ecthyma gangrenosum**, whether caused by direct inoculation or secondary to septicemia, begin as pink macules and progress to hemorrhagic nodules and eventually to ulcers with ecchymotic and gangrenous centers with eschar formation, surrounded by an intense red areola.

Outbreaks of dermatitis and urinary tract infections caused by *P. aeruginosa* have been reported in healthy persons after use of community swimming pools, wading pools, recreational whirlpools, or family-owned hot tubs. Skin lesions of folliculitis develop several hours to 2 days after contact with these water sources. Skin lesions may be erythematous, macular, papular, or pustular. Illness may vary from a few scattered lesions to extensive truncal involvement. In some children, malaise, fever, vomiting, sore throat, conjunctivitis, rhinitis, and swollen breasts may be associated with dermal lesions.

Pseudomonads other than *P. aeruginosa* rarely cause disease in healthy children, but pneumonia and abscesses due to *B. cepacia*, otitis media due to *P. putrefaciens* or *P. stutzeri*, abscesses due to

TABLE 188.1-1 -- *Pseudomonas aeruginosa* Infections

Infection	Common Clinical Characteristics
Endocarditis	Native right-sided (tricuspid) valve disease with intravenous drug abuse
Pneumonia	Compromised local (lung) or systemic host defense mechanisms. Nosocomial (respiratory), bacteremic (malignancy), or abnormal mucociliary clearance (cystic fibrosis) may be pathogenetic. Cystic fibrosis is associated with mucoid *Pseudomonas aeruginosa* organisms producing capsular slime.
Central nervous system infection	Meningitis, brain abscess; contiguous spread (mastoiditis, dermal sinus tracts, sinusitis); bacteremia or direct inoculation (trauma, surgery)
External otitis	Swimmer's ear; humid warm climates, swimming pool contamination
Malignant otitis externa	Invasive, indolent, febrile toxic, destructive necrotizing lesion in young infants, immunosuppressed neutropenic patients, or diabetic patients; associated with 17th nerve palsy and mastoiditis
Chronic mastoiditis	Ear drainage, swelling, erythema; perforated tympanic membrane
Keratitis	Corneal ulceration; contact lens keratitis
Endophthalmitis	Penetrating trauma, surgery, penetrating corneal ulceration; fulminant progression

Osteomyelitis/septic arthritis	Puncture wounds of foot and osteochondritis; intravenous drug abuse; fibrocartilaginous joints, sternum, vertebrae, pelvis; open fracture osteomyelitis; indolent; pyelonephritis and vertebral osteomyelitis
Urinary tract infection	Iatrogenic, nosocomial; recurrent urinary tract infections in children, instrumented patients, and those with obstruction or stones
Intestinal tract infection	Immunocompromise, neutropenia, typhlitis, rectal abscess, ulceration, rarely diarrhea; peritonitis in peritoneal dialysis
Ecthyma gangrenosum	Metastatic dissemination; hemorrhage, necrosis, erythema, eschar, discrete lesions with bacterial invasion of blood vessels; also subcutaneous nodules, cellulitis, pustules, deep abscesses
Primary and secondary skin infections	Local infection; burns, trauma, decubitus ulcers, toe web infection, green nail (paronychia); whirlpool dermatitis: diffuse, pruritic, folliculitis, vesiculopustular or maculopapular, erythematous lesions

P. fluorescens, and cellulitis and septicemia and osteomyelitis due to *S. maltophilia* have been reported. Septicemia and endocarditis due to *S. maltophilia* have also been associated with intravenous abuse of drugs.

BURNS AND WOUND INFECTION.

The surfaces of burns or wounds are frequently populated by *Pseudomonas* and other gram-negative organisms; this initial colonization with a low number of adherent organisms is a necessary prerequisite to invasive disease. Administration of antibiotics may diminish the susceptible microbiologic flora, permitting strains of relatively resistant *Pseudomonas* to flourish. Multiplication of organisms in devitalized tissues or associated with prolonged use of intravenous or urinary catheters increases the risk of septicemia with *P. aeruginosa*, a major problem in burned patients (Chapter 62).

CYSTIC FIBROSIS.

P. aeruginosa is common in children with cystic fibrosis; prevalence increases with increasing age and severity of pulmonary disease (Chapter 393). Mucoid strains of *P. aeruginosa* predominate in patients with cystic fibrosis but are rarely encountered in other conditions. The infection begins insidiously or even asymptomatically, and the progression has a highly variable pace. In children with cystic fibrosis, antibody does not eradicate the organism and antibiotics are only partially effective, thus, infection becomes chronic. After repeated courses of antibiotic treatment the *P. aeruginosa* strains may be highly antibiotic-resistant.

IMMUNOCOMPROMISED PERSONS.

Children with leukemia or other debilitating malignancies, particularly those who are receiving immunosuppressive therapy and who are neutropenic, are extremely susceptible to septicemia due to invasion of the bloodstream by *Pseudomonas* with which the patient is already colonized, usually in the respiratory or gastrointestinal tract. Signs of sepsis are often accompanied by a generalized vasculitis, and hemorrhagic necrotic lesions may be found in all organs, including the skin, where they appear as purple nodules or ecchymotic areas that become gangrenous (ecthyma gangrenosum). Hemorrhagic or gangrenous perirectal cellulitis or abscesses may occur, associated with ileus and profound hypotension.

NOSOCOMIAL PNEUMONIA.

Although not a significant cause of community-acquired pneumonia in children, *P. aeruginosa* is an important cause of nosocomial pneumonia, especially ventilator-associated pneumonia. *P. aeruginosa* has historically been found to contaminate ventilators, tubing, and humidifiers, but this is uncommon today with appropriate disinfection and routine changing of equipment. Nevertheless, colonization of the upper respiratory tract and the gastrointestinal tract may be followed by aspiration of *P. aeruginosa*-contaminated secretions, resulting in severe pneumonia. One of the most challenging situations is distinguishing between colonization and pneumonia in intubated patients. This can often only be resolved by using invasive culture techniques such as bronchoscopy with bronchial brushing.

INFANTS.

P. aeruginosa is an occasional cause of nosocomial bacteremia in newborns and accounts for 2–5% of positive blood culture results in neonatal intensive care units. A frequent focus preceding bacteremia is conjunctivitis. *P. aeruginosa* has been isolated increasingly from peritoneal fluid in infants with necrotizing enterocolitis. Older infants may occasionally present with community-acquired sepsis due to *P. aeruginosa*, but this is uncommon. In the few reports describing this sepsis, preceding conditions included ecthyma-like skin lesions, virus-associated transient neutropenia, and prolonged contact with contaminated bath water.

Diagnosis.

P. aeruginosa infection is rarely clinically distinctive. Diagnosis depends on recovery of the organism from the blood, cerebrospinal fluid, urine, or needle aspirate of the lung or from purulent material obtained by aspiration of subcutaneous abscesses or areas of cellulitis. An exception is ecthyma gangrenosum, which is characteristic of *Pseudomonas* infection of the skin. Rarely, similar skin lesions may follow septicemia due to *Aeromonas hydrophila*, other gram-negative bacilli, and *Aspergillus*.

Treatment.

Systemic infections with *Pseudomonas* should be treated promptly with an antibiotic to which the organism is susceptible in vitro. Response to treatment may be limited,

and prolonged treatment may be necessary for systemic infection in immunocompromised hosts.

Septicemia and other aggressive infections should be treated with either one or two bactericidal agents. Little evidence shows that more than one agent is needed for individuals with normal immunity or when treating urinary tract infections, but dual therapy is often used for a synergistic effect in immunocompromised patients or when the susceptibility of the organism is in doubt. Appropriate single agents include ceftazidime, cefoperazone, ticarcillin-clavulanate, and piperacillin-tazobactam. Gentamicin or another aminoglycosides may be used concomitantly for synergistic effect. Carbenicillin, ticarcillin, and mezlocillin alone are not recommended because strains of the organism rapidly become resistant to these agents.

Ceftazidime has proved to be extremely effective in patients with cystic fibrosis (150–250?mg/kg/24?hr divided q 6–8?hr IV). Azlocillin, mezlocillin, or piperacillin-tazobactam (300–450?mg/kg/24?hr divided q 6–8?hr IV) also have proved to be effective therapy for susceptible strains of *P. aeruginosa* when combined with an aminoglycoside. Additional effective antibiotics include imipenem-cilastatin, meropenem, and aztreonam. Ciprofloxacin, is effective but not approved in the United States for persons <18 yr of age. It is important to base continued treatment on the results of susceptibility tests because antibiotic resistance of *P. aeruginosa* to one or more antibiotics is increasing.

Meningitis is best treated with ceftazidime in combination with gentamicin, given intravenously. Concomitant intraventricular or intrathecal treatment with gentamicin (1–2?mg once daily, independent of body weight, until the cerebrospinal fluid is sterile) may be required when intravenous therapy fails but is not recommended for routine use.

Prognosis.

The prognosis is dependent in large part on the nature of the underlying disease. In severely immunocompromised patients, the prognosis for patients with *P. aeruginosa* sepsis is poor, unless susceptibility factors such as neutropenia or hypogammaglobulinemia can be reversed. The outcome is improved by combined antimicrobial therapy, a urinary tract portal of entry, absence of neutropenia or recovery from neutropenia, and drainage of local sites of infection. *Pseudomonas* is recovered from the lungs of most children who die of cystic fibrosis and may be responsible for the slow deterioration of these patients; *B. cepacia*, which is frequently resistant to standard antimicrobial agents, has been associated with a more rapid decline in pulmonary function and lower survival rate. The prognosis for normal development is poor in the few infants who survive *Pseudomonas* meningitis.

Prevention.

Prevention of infections due to *P. aeruginosa* is not a concern for healthy individuals outside of the hospital but is dependent on limiting contamination of the health care environment and preventing transmission to patients. Effective hospital infection control programs are necessary to identify and eradicate sources of the organism as quickly as possible. *Pseudomonas* may grow in distilled water, some disinfectants, parenteral alimentation solutions, and medications. In newborn nurseries, infection generally has been transmitted to the infants by the hands of personnel, from washbasin surfaces, from catheters, and from solutions used to rinse suction catheters.

Strict attention to handwashing, particularly with an iodophor-containing solution or alcohol-based hand rubs, before and between contacts with neonates, may prevent or interdict

---

epidemic disease. Meticulous care and sterile procedures in suctioning of endotracheal tubes, insertion and care of indwelling catheters, preparation of intravenous solutions, especially those for total parenteral alimentation, and regular replacement of intravenous administration tubing greatly reduce the hazard of extrinsic contamination by *Pseudomonas* and other gram-negative organisms.

Prevention of follicular dermatitis caused by *Pseudomonas* contamination of whirlpools or hot tubs is possible by maintaining pool water at a pH of 7.2–7.8 and free chlorine concentration at 70.5?mg/L.

Infections in burned patients may be minimized by protective isolation, debridement of devitalized tissue, and topical application of sulfadiazine or 10% mafenide acetate cream. Administration of intravenous immunoglobulin may be used. Approaches under investigation to prevent infection include development of *Pseudomonas* vaccine and development of hyperimmune globulin.

Pseudomonas infection of dermal sinuses communicating with the cerebrospinal space can be prevented by early identification and surgical repair. *Pseudomonas* infection of the urinary tract may be minimized or prevented by early identification and corrective surgery of obstructive lesions.

188.2 *Burkholderia*

B. cepacia.

B. cepacia is a filamentous gram-negative rod. It may be difficult to isolate from respiratory specimens in the laboratory, requiring an enriched, selective media (OFPBL) and as long as 3 days of incubation.

B. cepacia is a classic opportunist that rarely infects normal tissue but can be a pathogen for individuals with pre-existing damage to respiratory epithelium, especially persons with cystic fibrosis. Resistance to many antibiotics appears to be a factor in its emergence as a nosocomial pathogen. Although it is found throughout the environment, human-to-human spread among patients with cystic fibrosis occurs either directly by inhalation of aerosols or indirectly from contaminated equipment or surfaces. This has led to cohorting of patients with cystic fibrosis in some clinics, hospital wards, and social gatherings on the basis of *B. cepacia* colonization. *B. cepacia* in persons with cystic fibrosis may only represent colonization in many patients but in some it is associated with an acute respiratory syndrome of fever,

leukocytosis, and progressive respiratory failure. This is in contradistinction to *P. aeruginosa* in cystic fibrosis, which is insidious and less communicable.

Treatment in hospitals should include standard precautions and avoidance of placing colonized and uncolonized patients in the same room. Persons who have cystic fibrosis and who visit or provide care and are not infected or colonized with *B. cepacia* may elect to wear a mask when within 3?ft of a colonized patient. The use of antibiotics is guided by susceptibility studies of a patient's isolates because the susceptibility pattern of this species is quite variable. Ureidopenicillins (e.g., mezlocillin, piperacillin), aminoglycosides, ceftazidime, ciprofloxacin, and trimethoprim-sulfamethoxazole frequently show good activity. Resistance to aminoglycosides is the rule and presence of inducible ß-lactamase in many strains is probably the cause of clinical failures reported with ureidopenicillins and ceftazidime. Treatment with two or three agents may be necessary to control the infection and avoid the development of resistance.

B. mallei (Glanders).

Glanders is a severe infectious disease of horses and other domestic and farm animals due to *B. mallei*, a nonmotile gram-negative bacillus that is occasionally transmitted to humans. It is acquired by inoculation into the skin, usually at the site of a previous abrasion, or by inhalation of aerosols. Laboratory workers may acquire it from clinical specimens. The disease is relatively common in Asia, Africa, and the Middle East. The clinical manifestations include septicemia, acute or chronic pneumonitis, and hemorrhagic necrotic lesions of the skin, nasal mucous membranes, and lymph nodes. Glanders is treated with sulfadiazine, tetracycline, or chloramphenicol and streptomycin over a period of many months. Interest in this organism has increased due to the possibility of its use as a bioterrorism agent (Chapter 706).

B. pseudomallei (Melioidosis).

This important disease of Southeast Asia and northern Australia occurs in the United States mainly in persons returning from endemic areas. The causative agent is *B. pseudomallei*, an inhabitant of soil and water in the tropics. It is ubiquitous in endemic areas; infection follows inhalation of dust or direct contamination of abrasions or wounds. Human-to-human transmission has only rarely been reported. Serologic surveys demonstrate that asymptomatic infection occurs in endemic areas. The disease may remain latent and appear when host resistance is reduced, sometimes years after the initial exposure.

Melioidosis may present as a single primary skin lesion (vesicle, bulla, or urticaria). Pulmonary infection may be subacute and mimic tuberculosis or it may present as an acute necrotizing pneumonia. Occasionally, septicemia occurs and numerous abscesses are noted in various organs of the body. Myocarditis, pericarditis, endocarditis, intestinal abscess, cholecystitis, acute gastroenteritis, urinary tract infections, septic arthritis, paraspinal abscess, osteomyelitis, and generalized lymphadenopathy all have been observed. Melioidosis may also present as an encephalitic illness with fever and seizures.

Diagnosis is based on visualization of characteristic small gram-negative rods in exudates or growth on laboratory media such as eosin-methylene blue or MacConkey agar. Serologic tests are available, and diagnosis can be established by a fourfold or greater increase in antibody titer in an individual with an appropriate syndrome.

B. pseudomallei is susceptible to many antimicrobial agents, including third-generation cephalosporins, aminoglycosides, tetracycline, cotrimoxazole, sulfisoxazole, chloramphenicol, and amoxicillin-clavulanate. Therapy should be guided by antimicrobial susceptibility tests; two or three agents such as ceftazidime or chloramphenicol plus either trimethoprim-sulfamethoxazole, sulfisoxazole, or an aminoglycoside are usually chosen for severe or septicemic disease. For severe disease, prolonged treatment of 2–6 mo is recommended to prevent relapses. Appropriate antibiotic therapy generally results in recovery.

188.3 *Stenotrophomonas*

S. maltophilia (formerly *Xanthomonas maltophilia* or *Pseudomonas maltophilia)* is a short to medium-sized straight gram-negative bacillus. It is ubiquitous in nature and can be found in the hospital environment. Strains isolated in the laboratory may be contaminants, may be a commensal from the colonized surface of a patient, or may represent an invasive pathogen. The species is an opportunist; serious infections usually afflict those requiring intensive care, typically patients with ventilator-associated pneumonia or catheter-associated infections. Prolonged antibiotic exposure appears to be a frequent factor in nosocomial *S. maltophilia* infections, probably due to its endogenous antibiotic resistance pattern. Common types of infection include pneumonia, urinary tract infection, endocarditis, and osteomyelitis. Strains vary as to antibiotic susceptibility. Treatment should be based on the results of susceptibility testing. Trimethoprim-sulfamethoxazole, minocycline, doxycycline, ticarcillin-clavulanate, and chloramphenicol frequently show good activity. Trimethoprim-sulfamethoxazole is usually the drug combination of choice. Aminoglycosides, cephalosporins, and carbapenems are usually inactive. Among the quinolone antibiotics, ciprofloxacin often has good activity and has been used clinically, and the newer agents

sparfloxacin and levofloxacin usually show good activity in vitro. **REFERENCES**

Chapter 189 - Tularemia (*Francisella tularensis*)

Gordon E. Schutze
Richard F. Jacobs

Tularemia is a zoonotic infection caused by the gram-negative bacterium *Francisella tularensis*. Tularemia is primarily a disease of wild animals; human disease is incidental and usually results from contact with blood-sucking insects or wild animals. The illness caused by *F. tularensis* is manifested by different clinical syndromes, the most common of which consists of an ulcerative lesion at the site of inoculation with regional lymphadenopathy or lymphadenitis.

Etiology.

F. tularensis, the causative agent of tularemia, is a small, nonmotile, pleomorphic, gram-negative coccobacillus. The two main biovars are *F. tularensis* biovar *tularensis* (Jellison type A) and *F. tularensis* biovar *palearctica* (Jellison type B). Type A produces more serious disease in humans and is most commonly found in North America; type B may be found in North America, Europe, and Asia and produces a less virulent disease. Type A is associated with ticks and lagomorphs (i.e., rabbits, hares); type B can be associated with mosquitoes, rodents, and water and marine animals.

Epidemiology.

During 1990–2000, a total of 1,368 cases of tularemia were reported in the United States from 44 states, averaging 124 cases (range: 86–193) per year (Fig. 189–1). Four states accounted for 56% of all reported tularemia cases: Arkansas, 315 cases (23%); Missouri, 265 cases, (19%); South Dakota, 96 cases (7%); Oklahoma, 90 cases, (7%).

TRANSMISSION.

Of all the zoonotic diseases, tularemia is unusual because of the different modes of transmission of disease. A large number of animals serve as a reservoir for this organism, which can penetrate both intact skin and mucous membranes. Transmission can occur through the bite of infected ticks or other biting insects, by contact with infected animals or their carcasses, by consumption of contaminated

foods or water, or through inhalation, as might occur in a laboratory setting. This organism is not, however, transmitted from person to person. In the United States, rabbits and ticks are the principal reservoirs. Most disease due to rabbit exposure occurs in the winter, and disease due to tick exposure occurs in the warmer months (April–September). *Amblyomma americanum* (Lone Star tick), *Dermacentor variabilis* (dog tick), and *Dermacentor andersoni* (wood tick) are the most common tick vectors. These ticks usually feed on infected small rodents and later feed on humans. Taking that blood meal through a fecally contaminated field transmits the infection.

Pathogenesis.

The most common portal of entry for human infection is through the skin or mucous membrane. This may occur through the bite of an infected insect or by way of inapparent abrasions. Inhalation or ingestion of *F. tularensis* can also result in infection. More than 10^8 organisms are usually required to produce infection if they are ingested, but as few as 10 organisms may cause disease if they are inhaled or injected into the skin. Within 48–72?hr after injection into the skin, an erythematous, tender, or pruritic papule may appear at the portal of entry. This papule may enlarge and form an ulcer with a black base, followed by regional lymphadenopathy. Once *F. tularensis* reaches the lymph nodes, the organism may multiply and form granulomas. Bacteremia may also be present, and although any organ of the body may be involved, the reticuloendothelial system is the most commonly affected.

Conjunctival inoculation may result in infection of the eye with preauricular lymphadenopathy (**Parinaud oculoglandular syndrome**). Inhalation, aerosolization, or hematogenous spread of the organisms can result in pneumonia. Chest roentgenograms of such patients may reveal patchy infiltrates rather than areas of consolidation. Pleural effusions may also be present and may contain blood. In pulmonary infections, mediastinal adenopathy may be present; in oropharyngeal disease, patients may develop cervical lymphadenopathy. Typhoidal tularemia may be used to describe severe bacteremic disease, regardless of the mode of transmission or portal of entry.

Infection with tularemia stimulates the host to produce antibodies. This antibody response, however, has only a minor role in fighting this infection. The body is dependent on cell-mediated immunity to contain and eradicate this infection. Infection is usually followed by specific protection; thus, chronic infection or reinfection is unlikely.

Clinical Manifestations.

Although it may vary, the average incubation period from infection until clinical symptoms appear is 3 days (range, 1–21 days). A sudden onset of fever with other associated symptoms is common (Table 189–1). Physical examination may include lymphadenopathy, hepatosplenomegaly, or skin lesions. Various skin lesions have been described, including erythema multiforme and erythema nodosum. Approximately 20% of patients may develop a generalized maculopapular rash that occasionally becomes pustular. These clinical manifestations of tularemia have been divided into various syndromes (Table 189–2).

Ulceroglandular and glandular disease are the two most common forms of tularemia diagnosed in children. The most common glands involved are usually the cervical or posterior auricular nodes owing to a tick bite on the head or neck. If an ulcer is present, it is erythematous and painful and may last from 1–3 wk. The ulcer is located at the portal of entry. After the ulcer develops, regional lymphadenopathy ensues. These nodes

---

Figure 189-1 Reported cases of tularemia in the United States from 1990–2000, based on 1,347 patients reporting county of residence in the lower continental Unites States. Alaska reported ten cases in four counties during 1990–2000. The circle size is proportional to the number of cases, ranging from 1–39 cases. (*From Centers for Disease Control and Prevention: Tularemia—United States, 1990–2000. MMWR 2002;51:181–4.*)

TABLE 189-1 -- **Common Clinical Manifestations of Tularemia in Children**

Sign or Symptom	Frequency (%)
Lymphadenopathy	96
Fever (>38.3°C)	87
Ulcer/eschar/papule	45
Pharyngitis	43
Myalgias/arthralgias	39
Nausea/vomiting	35
Hepatosplenomegaly	35

may vary in size from 0.5–10?cm and may appear singly or in clusters. These affected nodes may become fluctuant and drain spontaneously, but most usually resolve with treatment. Late suppuration of the involved nodes has been described in 25–30% of patients despite effective therapy. Examination of this material from such lymph nodes usually reveals sterile necrotic material.

Pneumonia due to *F. tularensis* usually presents as variable parenchymal infiltrates that are unresponsive to ß-lactam antimicrobial agents. Inhalation-related infection has been described in laboratory workers who are working with the organism; it results in a relatively high mortality rate. Aerosols from farming activities involving rodent contamination (e.g., haying, threshing)

TABLE 189-2 -- **Clinical Syndromes of Tularemia in Children**

Clinical Syndrome	Frequency (%)

Typhoidal	2
Other*	6

Includes meningitis, pericarditis, hepatitis, peritonitis, endocarditis, osteomyelitis.

or carcass destruction with lawnmowers have been reported to cause pneumonia as well. Patchy parenchymal infiltrates can also be demonstrated in other forms of tularemia. Patchy segmental infiltrates, hilar adenopathy, and pleural effusions are the most common abnormalities demonstrated on chest roentgenograms. Patients may also complain of a nonproductive cough, dyspnea, or pleuritic chest pain.

Oropharyngeal tularemia results from consumption of poorly cooked meats or contaminated water. This syndrome is characterized by acute pharyngitis, with or without tonsillitis, and cervical adenitis. Infected tonsils may become large and develop a yellowish-white membrane that may resemble the membranes associated with diphtheria. Gastrointestinal disease may also occur and usually presents with mild, unexplained diarrhea but may progress to rapidly fulminant and fatal disease.

Oculoglandular tularemia is uncommon, but when it does occur, the portal of entry is the conjunctiva. Contact with contaminated fingers or debris from crushed insects is the most common way of applying the organisms to the conjunctiva. The conjunctiva is painful and inflamed, with yellowish nodules and pinpoint ulcerations. This purulent conjunctivitis with regional lymphadenopathy (ipsilateral preauricular or submandibular nodes) is referred to as Parinaud oculoglandular syndrome.

Typhoidal tularemia is usually associated with a large inoculum of organisms and usually presents with fever, headaches, and signs or symptoms of endotoxemia. Patients typically are critically ill, and symptoms mimic those with other forms of sepsis. Clinicians practicing in tularemia-endemic regions must always consider this diagnosis in critically ill children.

Diagnosis.

The history and physical examination of the patient may suggest the diagnosis of tularemia, especially if the patient lives in or has visited an endemic region. A history of animal or tick exposure may be especially helpful. Hematologic blood tests are nondiagnostic. Results of routine cultures and smears are positive in only approximately 10% of cases. *F. tularensis* can be cultured in the microbiology laboratory on cysteine-glucose-blood agar, but care should be taken to alert the personnel in the laboratory if this is attempted so they can take the proper precautions to protect themselves from acquiring infection.

The diagnosis of tularemia is most commonly established through the use of a standard and highly reliable serum agglutination

test. In the standard tube agglutination test, a single titer of =1:160 in a patient with a compatible history and physical findings can establish the diagnosis. A fourfold increase in titer from paired serum samples collected 2–3 wk apart is also diagnostic. False-negative serologic responses can be obtained early in the infection, and as many as 30% of individuals require longer than 3 wk before testing positive. Once infected, patients may have a positive agglutination test result (1:20–1:80) that may persist for a lifetime.

Other testing techniques available include a microagglutination test, an enzyme-linked immunosorbent assay, an analysis of urine for tularemia antigen, and polymerase chain reaction. These techniques may become more popular in the future but at this time have a limited role in establishing the diagnosis of tularemia.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis of ulceroglandular or glandular tularemia includes cat-scratch disease *(Bartonella henselae)*; infectious mononucleosis; Kawasaki syndrome; lymphadenopathy due to *Staphylococcus aureus*, group A streptococcus, *Mycobacterium tuberculosis*, *Toxoplasma gondii*, and the nontuberculous mycobacteria, along with *Sporothrix schenckii*; plague; anthrax; melioidosis; and rat-bite fever. Oculoglandular disease may also occur with other infectious agents, such as *B. henselae, Treponema pallidum, Coccidioides immitis*, herpes simplex virus, adenovirus, and the bacterial agents responsible for purulent conjunctivitis. Oropharyngeal tularemia must be differentiated from the same diseases that cause ulceroglandular/glandular disease and from cytomegalovirus, herpes simplex, adenovirus, and other viral or bacterial etiologies. Pneumonic tularemia must be differentiated from the other non–ß-lactam-responsive organisms such as *Mycoplasma*, *Chlamydia*, mycobacteria, fungi, and rickettsia. Typhoidal tularemia must be differentiated from other forms of sepsis as well as from enteric fever (typhoid and paratyphoid fever) and brucellosis.

Treatment.

All strains of *F. tularensis* are susceptible to gentamicin and streptomycin. Gentamicin (5?m/kg/24?hr divided bid or tid IV or IM) has become the drug of choice for the treatment of tularemia in children because of the limited availability of streptomycin (30–40?mg/kg/24?hr divided bid IM) and the fewer adverse effects of gentamicin. Therapy is typically continued for 7–10 days, but in mild cases, 5–7 days may be sufficient. Chloramphenicol and tetracyclines have been used in the past, but the high relapse rate has limited their use in children. Early data suggested that *F. tularensis* would be susceptible to the third-generation cephalosporins (e.g., cefotaxime, ceftriaxone), but clinical case reports demonstrate a nearly universal failure rate with these agents. Quinolones are active against *F. tularemia* and have been used for treatment of the milder form of tularemia due to the European biovar *F. tularensis* biovar *palearctica*. Further data are required before quinolone therapy can be recommended for the most common biovar encountered in North America, *F.*

tularensis biovar *tularensis*.

Patients typically have defervescence within 24–48?hr after starting therapy, and relapses are uncommon if gentamicin or streptomycin is used. Patients who have not started on appropriate therapy early may respond more slowly to antimicrobial therapy. Late suppuration of involved lymph nodes may occur despite adequate therapy but usually contains sterile material.

Prognosis.

Poor outcomes are associated with a delay in recognition and treatment, but with rapid recognition and treatment fatalities are exceedingly rare. The mortality rate for severe untreated disease (e.g., pneumonia, typhoidal disease) can be as high as 30% in these situations, but in general, the overall mortality rate is <1%.

Prevention.

Prevention of tularemia is based on avoiding exposure. Children living in tick-endemic regions should be taught to avoid tick-infested areas, and families should have a tick control plan for their immediate environment and for their pets. Protective clothing should be worn when entering a tick-infested area, but more importantly, children should undergo frequent tick checks during and after their time in these areas. Skin repellents such as *N-N*-diethyl-M-toluamide (DEET) can be used but have been described to cause systemic reactions if used incorrectly on small infants. Avoiding taking young infants into tick-endemic regions is the most prudent approach. If DEET-containing compounds are used, they should be used sparingly on the exposed skin, avoiding the hands and face. The repellent should be washed off completely after leaving the high-risk region. Clothing repellents that use permethrin have been demonstrated to be an effective addition to the use of protective clothing. If ticks are found on the child, forceps should be used to pull the tick straight out. The skin should be cleansed before and after this procedure.

Children should also be taught to avoid sick and dead animals. Dogs and cats are most likely to bring these animals to a child's attention. Children should be encouraged to wear gloves while cleaning wild game. A vaccine is available for adults with high-risk vocations (e.g., veterinarians), but there are no recommendations for use in children. Prophylactic antimicrobial agents are not effective in preventing tularemia and should not be used after exposure.

Chapter 190 - *Brucella*

Gordon E. Schutze
Richard F. Jacobs

Human brucellosis, caused by organisms of the genus *Brucella*, continues to be a major public health problem worldwide. Humans are accidental hosts and acquire this zoonotic disease from direct contact with an infected animal or consumption of products of an infected animal. Although brucellosis is widely recognized as an occupational risk among adults working with livestock, much of the brucellosis in children is food-borne and is associated with consumption of unpasteurized milk products.

Etiology.

Brucella abortus (cattle), *B. melitensis* (goat/sheep), *B. suis* (swine), and *B. canis* (dog) are the most common organisms responsible for human disease. These organisms are small, aerobic, non–spore-forming, nonmotile, gram-negative coccobacillary bacteria that are fastidious in their growth but can be grown on various laboratory media including blood and chocolate agars. When brucellosis is suspected, however, the clinical laboratory should be alerted so the cultures can be maintained for =21 days to ensure growth if the organism is present.

Epidemiology.

Brucellosis exists worldwide but is especially prevalent in the Mediterranean basin, Arabian Gulf, the Indian subcontinent, and parts of Mexico and Central and South America. In industrialized countries, recreational or occupational exposure to infected animals is a major risk factor for the development of disease. Among children, however, geographic locations that are endemic for *B. melitensis* remain areas of

increased risk for the development of infection. In such locations, unpasteurized milk from goats or camels may be used to feed children, thus leading to the development of brucellosis. Consequently, a history of travel to endemic regions or consumption of exotic food or unpasteurized dairy or dairy products may be an important clue to the diagnosis of human brucellosis.

Pathogenesis.

Routes of infection for these organisms include inoculation through cuts or abrasions in the skin, inoculation of the conjunctival sac of the eye, inhalation of infectious aerosols, or ingestion of contaminated meat or dairy products. The risk of infection depends on the nutritional and immune status of the host, the route of inoculum, and the species of *Brucella*. For reasons that remain unclear, *B. melitensis* and *B. suis* tend to be more virulent than *B. abortus* or *B. canis*.

The major virulence factor for *Brucella* appears to be its cell wall lipopolysaccharide. Strains containing smooth lipopolysaccharide have been demonstrated to have greater virulence and are more resistant to killing by polymorphonuclear leukocytes. These organisms are facultative intracellular pathogens that can survive and replicate within the mononuclear phagocytic cells (monocytes, macrophages) of the reticuloendothelial system. Even though *Brucella* are chemotactic for leukocytes entry into the body, the leukocytes are less efficient in killing these organisms than other bacteria despite the assistance of serum factors such as complement.

Organisms that are not phagocytosed by the leukocytes are ingested by the macrophages and become localized within the reticuloendothelial system. Specifically, they reside within the liver, spleen, lymph nodes, and bone marrow and result in granuloma formation. Antibodies are produced against the lipopolysaccharide and other cell wall antigens. This provides a means of diagnosis and probably has a role in long-term immunity. The major factor in recovery from infection appears to be development of a cell-mediated response resulting in macrophage activation and enhanced intracellular killing. Specifically, sensitized T lymphocytes release cytokines (e.g., interferon-? and tumor necrosis factor a), which activate the macrophages and enhance their intracellular killing capacity.

Clinical Manifestations.

Brucellosis is a systemic illness that can be very difficult to diagnose in children without a history of animal or food exposure. Symptoms can be acute or insidious in nature and are usually nonspecific, beginning 2–4 wk after inoculation. Although the clinical manifestations do vary, the classic triad of fever, arthralgia/arthritis, and hepatosplenomegaly can be demonstrated in most patients. Other associated symptoms include abdominal pain, headache, diarrhea, rash, night sweats, weakness/fatigue, vomiting, cough, and pharyngitis. A common constellation of symptoms in children is refusal to eat, lassitude, refusal to bear weight, and failure to thrive. Besides hepatosplenomegaly, the physical findings on examination are usually few, with the exception of arthritis. The fever pattern can vary widely, and virtually any organ or tissue can be involved.

If abnormalities are demonstrated on physical examination, the bones and joint frequently are involved, with the sacroiliac joint as well as the hips, knees, and ankles being the most common. Although headache, mental inattention, and depression may be demonstrated in patients with brucellosis, invasion of the nervous system occurs in only about 1% of cases. Neonatal and congenital infections with these organisms have also been described. These have been transmitted

transplacentally, from breast milk, and through blood transfusions. The signs and symptoms associated with this infection are very vague and nonpathognomonic.

Diagnosis.

Routine laboratory examinations of the blood are not helpful, with the exception of the white blood cell count, which may be low or normal. A history of exposure to animals or ingestion of unpasteurized dairy products may be more helpful. A definitive diagnosis is established by recovering the organisms in the blood, bone marrow, or other tissues. Although automated culture systems and the use of the lysis-centrifugation method have shortened the isolation time from weeks to days, it is prudent to alert the clinical microbiology laboratory that brucellosis is suspected. Isolation of the organism still may require as long as 4 wk from a blood culture sample. Caution is also advised when using automated bacterial identification systems, because isolates have been misidentified as other gram-negative organisms (e.g., *Haemophilus influenzae* type b).

In the absence of positive culture results, various serologic tests have been applied to the diagnosis of brucellosis. The serum agglutination test (SAT) is the most widely used and detects antibodies against *B. abortus*, *B. melitensis*, and *B. suis*. This method does not detect antibodies against *B. canis* because this organism lacks the smooth lipopolysaccharide. No single titer is ever diagnostic, but most patients with acute infections have titers of =1:160. Low titers may be found early in the course of the illness, requiring the use of acute and convalescent sera testing to confirm the diagnosis. Because patients with active infection have both an IgM and an IgG response and the SAT measures the total quantity of agglutinating antibodies, the total quantity of IgG is measured by treatment of the serum with 2-mercaptoethanol. This fractionation is important in determining the significance of the antibody titer because low levels of IgM can remain in the serum for weeks to months after the infection has been treated. It is important to remember that all titers must be interpreted in light of a patient's history and physical examination. False-positive results due to cross-reacting antibodies to other gram-negative organisms such as *Yersinia enterocolitica*, *Francisella tularensis*, and *Vibrio cholerae* can occur. In addition, the prozone effect can give false-negative results in the presence of high titers of antibody. To avoid this issue, serum that is being tested should be diluted to =1:320.

Among newer tests, the enzyme immunoassay appears to be the most sensitive method for detecting *Brucella* antibodies. Polymerase chain reaction assays are also becoming available but at this time are mostly limited to research facilities.

DIFFERENTIAL DIAGNOSIS.

Brucellosis may be confused with other infections such as tularemia, cat-scratch disease, typhoid fever, and fungal infections due to histoplasmosis, blastomycosis, or coccidioidomycosis. Infections due to *Mycobacterium tuberculosis*, atypical mycobacteria, rickettsiae, and *Yersinia* can present in a similar fashion to brucellosis.

Treatment.

Many antimicrobial agents are active in vitro against the *Brucella* species, but the clinical effectiveness does not always correlate with these results. Doxycycline is the most useful antimicrobial agent and, when combined with an aminoglycoside, is associated with the fewest relapses (Table 190–1). Treatment failures with ß-lactam antimicrobial agents, including the third-generation cephalosporins, may be due to the intracellular nature of the organism. Agents that provide intracellular killing are required for eradication of this infection. Similarly, it is apparent that prolonged treatment is the key to preventing disease relapse. Relapse is confirmed by isolation of *Brucella* within weeks to months after therapy has ended and is usually not associated with antimicrobial resistance.

The onset of initial antimicrobial therapy may precipitate a Jarisch-Herxheimer–like reaction presumably due to a large antigen load. It is rarely severe enough to require corticosteroid therapy.

Prognosis.

Before the use of antimicrobial agents, the course of brucellosis was often prolonged and may have led to death. Since the institution of specific therapy, most deaths are due to specific organ system involvement (e.g., endocarditis) in complicated cases. The prognosis after specific therapy is excellent if patients are compliant with the prolonged therapy.

TABLE 190-1 -- Recommended Therapy for the Treatment of Brucellosis

Age and Condition	Antimicrobial Agent	Dose	Route	Duration
=9 yr	Doxycycline + Streptomycin or Gentamicin *Alternative*: Doxycycline + Rifampin	200?mg/24 hr 1 g/24 hr 3–5?mg/kg/24 hr 200?mg/24 hr 600–900?mg/24 hr	PO IM IM/IV PO PO	6 wk 1–2 wk 1–2 wk 6 wk 6 wk
< 9 yr	TMP-SMZ + Rifampin	Trimethoprim (10?mg/kg/24 hr; maximum: 480?mg/24 hr) and sulfamethoxazole (50?mg/kg/24 hr; maximum: 2.4 gr/24 hr) + 15–20?mg/kg/24 hr	PO PO	45 days 45 days

Meningitis, osteomyelitis, endocarditis	Doxycycline + Gentamicin +/- Rifampin	200?mg/24 hr 3–5?mg/kg/24 hr Same as above	PO IV PO	4–6 mo 4–6 mo 4–6 mo

Prevention.

Prevention of brucellosis is dependent on effective eradication of the organism from cattle, goats, and swineherds as well as from other animals. Pasteurization of milk and dairy products for human consumption remains an important aspect of prevention. No vaccine currently exists for use in children; therefore, education of the public continues to have a prominent role in prevention of this disease.

Chapter 191 - *Legionella*

Lucy Tompkins

Legionellosis comprises **legionnaires' disease** (pneumonia), other invasive extrapulmonary infections, and an acute flulike illness known as **Pontiac fever**. In contrast to the syndromes associated with invasive disease, Pontiac fever is a self-limiting illness that develops after aerosol exposure and may represent a toxic or hypersensitivity response to *Legionella*.

Etiology.

Legionellaceae are aerobic, non–spore-forming unencapsulated gram-negative bacilli that stain poorly with Gram stain when performed on smears from clinical specimens. Microorganisms in tissue can be better visualized with the Gimenez or silver stains (Dieterle or Warthin-Starry). Stained smears of *Legionella pneumophila* taken from colonial growth resemble *Pseudomonas*. Unlike other *Legionella* species, *L. micdadei* stains acid fast. Although more than 30 species of the genus have now been identified, the majority (90%) of clinical infections are caused by *L. pneumophila*, and most of the remainder are caused by *L. micdadei, L. bozemanii, L. dumoffii*, and *L. longbeachae*.

The organisms are fastidious and require l-cysteine, ferric ion, and a-keto acids for growth. Colonies develop within 3–5 days on buffered charcoal yeast extract agar, which may contain selected antibiotics to inhibit overgrowth by other microorganisms; *Legionella* rarely grows on routine laboratory media.

Epidemiology.

Fresh water (e.g., lakes, streams, thermally polluted waters, potable water) is the environmental reservoir of *Legionella* in nature, and invasive pneumonia (legionnaires' disease) is related to exposure to potable water or to aerosols containing the bacteria. Growth of *Legionella* occurs more readily in hot water, and exposure to warm water sources is an important risk factor for disease. *Legionella* organisms are facultative intracellular parasites and grow inside protozoans present in biofilms consisting of organic and inorganic material found in plumbing and water storage tanks and various other bacterial species. Sporadic cases of community-acquired legionnaires' disease can be attributed to potable water in the

local environment of the patient. Risk factors for acquisition of sporadic community-acquired pneumonia include nonmunicipal water supply, residential plumbing repairs, and lower water heater temperatures, which facilitate growth of bacteria or lead to release of a bolus of biofilm containing *Legionella* into potable water. The mode of transmission may be by way of inhalation of aerosols or by aspiration. Outbreaks of legionnaires' disease have been associated with protozoans in the implicated water source; replication within these eukaryotic cells presumably amplifies and maintains *Legionella* within the potable water distribution system. Outbreaks of community-acquired pneumonia and some nosocomial outbreaks have been linked to common sources, including potable hot water heaters, evaporative condensers cooling towers, whirlpool baths, humidifiers, and nebulizers.

Hospital-acquired infections are most often linked to potable water. Exposure may occur through two general mechanisms: (1) aspiration of ingested microorganisms, including those in gastric feedings, that are mixed with contaminated tap water; and (2) aerosols from showers and sinks. Extrapulmonary legionellosis may occur through topical application of contaminated tap water into surgical or traumatic wounds. In contrast to legionnaires' disease, Pontiac fever outbreaks have occurred through exposure to aerosols from whirlpool baths, ultrasonic humidifiers, and ventilation systems.

The incidence of community-acquired legionnaires' disease caused by *L. pneumophila* occurring sporadically in adults is estimated at 7–20 cases/100,000 per year and demonstrates geographic differences. *Legionella* infections have no seasonal pattern. Approximately 0.5–5.0% of those exposed to a common source develop pneumonia, whereas the attack rate in Pontiac fever outbreaks is very high (85–100%). In one large community-based study of adults, *Legionella* was associated with 3% of pneumonia cases. Taken together, *Mycoplasma pneumoniae, Chlamydia pneumoniae*, and *L. pneumophila* accounted for 10–38% of all community-acquired pneumonia. Therefore, current clinical guidelines for community-acquired pneumonia recommend empirical therapy with macrolides or quinolones.

As estimated by seroconversion to *L. pneumophila* among children hospitalized with pneumonia, the legionnaires' disease rate was found to be quite low. Community-acquired pneumonia occurs most often in children >4 yr of age. Most nosocomial infections have been reported as case reports; therefore, the true incidence of disease in children is unknown. Nosocomial infection rates in adults are difficult to determine because many hospital laboratories do not attempt to isolate *Legionella* by culture. Hospital-acquired legionellosis in children is associated with clinical risk factors and with environmental exposure. Acquisition of antibodies to *L. pneumophila* in healthy children occurs progressively over time, although this presumably reflects subclinical infection or mild respiratory disease or antibodies that cross react with other bacterial species.

Pathogenesis.

Legionella organisms are facultative intracellular parasites of eukaryotic cells. In humans, the target cell is the alveolar macrophage, although other cell types may also be invaded. Although *Legionella* can be grown on artificial media, the intracellular environment provides the definitive site of growth. Growth in macrophages occurs to the point of cell death, followed by reinfection of new cells, until these cells are activated and can subsequently kill intracellular microorganisms. Acute, severe infection of the lung provokes an acute inflammatory response and necrosis; early on, more bacteria are found in extracellular spaces. Subsequently, macrophage activation and other immune responses produce intense infiltration of tissue by macrophages that contain intracellular bacteria. Corticosteroid therapy poses a high risk of infection by interfering with T cell and macrophage function. Legionnaires' disease rarely occurs in healthy immunocompetent patients with no evidence of respiratory tract disease or dysfunction.

Although certain bacterial factors have been postulated to have a role in virulence, the contribution of each of these to overall pathogenesis is unclear. As in other diseases caused by facultative intracellular microorganisms, the outcome is critically dependent on the specific and nonspecific immune responses of the host, in particular, macrophage and T-cell responses.

Clinical Manifestations.

Legionnaires' disease was originally believed to cause a clinical syndrome called atypical pneumonia and was associated with extrapulmonary signs and symptoms, including diarrhea, hyponatremia, hypophosphatemia, abnormal results of liver function tests, confusion, and renal dysfunction. Although a subset of patients may exhibit “classic” manifestations, *Legionella* infection typically causes pneumonia that is indistinguishable from disease produced by other infectious agents. Fever, cough, and chest pain are common presenting symptoms; the cough may be productive of purulent sputum or may be nonproductive. Although the classic chest radiographic appearance showed rapidly progressive alveolar filling infiltrates, in usual cases of pneumonia the chest radiographic appearance is widely variable, appearing as tumor-like shadows, evidence of nodular infiltrates, unilateral or bilateral infiltrates, or cavitation, although cavitation is rarely seen in non-immunocompromised patients. This picture overlaps substantially with disease caused by *Streptococcus pneumoniae*. Although pleural effusion is less commonly associated with legionnaires' disease, its frequency varies so widely that neither the presence or absence of effusion is helpful in differential diagnosis. If present, pleural fluid should be obtained for culture.

A few clinical features may help to differentiate *Legionella* pneumonia from other causes. *Legionella* pneumonia produces an acute-onset febrile illness, the radiograph shows alveolar filling infiltrates, and there is no clinical response to broad-spectrum ß-lactam (penicillins and cephalosporins) or aminoglycoside antibiotics.

Concomitant infection with other pathogens occurs in 5–10% of cases of legionnaires' disease; therefore, culture of another potential pulmonary pathogen does not preclude the diagnosis of legionellosis.

Reports of nosocomial *Legionella* pneumonia in children demonstrate that rapid onset, temperature greater than 38.5℃, cough, pleuritic chest pain, and dyspnea are present in most. Abdominal pain, headache, and diarrhea are also common. Chest

radiographs reveal lobar consolidations or diffuse bilateral infiltrates, and pleural effusions are noted. Symptoms do not respond to treatment with ß-lactam antibiotics or aminoglycosides.

Risk factors for legionnaires' disease in adults include chronic diseases of the lung (e.g., smoking, bronchitis), older age, diabetes and renal failure, immunosuppression associated with organ transplantation, corticosteroid therapy, and episodes of aspiration. The number of reported cases of community-acquired legionnaires' disease in children is small. Among these, immunocompromised status, especially corticosteroid treatment, coupled with exposure to contaminated potable water, are the major risk factors. Infection in a few children with chronic pulmonary disease without immune deficiency has also been reported but infection in children lacking any risk factors is very uncommon. The modes of transmission of community-acquired disease in children include exposure to mists, water coolers, and other aerosol-generating apparatuses. Nosocomial *Legionella* infection occurs more frequently than community-acquired disease in children, and the modes of acquisition include microaspiration, frequently associated with nasogastric tubes, and aerosol inhalation. Bronchopulmonary *Legionella* infections occur in patients with cystic fibrosis and have been associated with aerosol therapy or mist tents. Legionnaires' disease is also reported in pediatric patients with asthma and tracheal stenosis. Chronic steroid therapy for asthma is a reported risk factor for *Legionella* infections in children.

Pontiac fever in adults and children is characterized by high fever, myalgia, headache, and extreme debilitation, lasting for a few days. Cough, breathlessness, diarrhea, confusion, and chest pain may occur, but there is no evidence for invasive infection. The disease is self-limited without sequelae. Virtually all exposed individuals seroconvert to *Legionella* antigens. A very large outbreak in Scotland that affected 35 children was attributed to *L. micdadei*, which was isolated from a whirlpool spa. The onset of illness was 1–7 days (median, 3 days), and all exposed children developed significant titers of specific antibodies to *L. micdadei*. The pathogenesis of Pontiac fever is not known. In the absence of evidence of true infection, the most likely hypothesis is that this syndrome is caused by a toxic or hypersensitivity reaction to microbial, or protozoan, antigens.

Diagnosis.

Culture of *Legionella* from sputum, other respiratory tract specimens, blood, or tissue is the gold standard against which indirect methods of detection should be compared. Specimens obtained from the respiratory tract that are contaminated with oral flora must be treated and processed to reduce contaminants and plated onto selective media. Because these are costly and time-consuming methods, many laboratories do not process specimens for culture. The urinary antigen assay that detects *L. pneumophila* serogroup I has 80% sensitivity and

99% specificity. Thus, the assay is a useful method in the prompt diagnosis of legionnaires' disease caused by this serogroup, which accounts for the majority of symptomatic infections. In the United States, this test is frequently used because it is widely available in reference laboratories. The microorganisms can also be identified presumptively by direct immunofluorescence antibody screening, although the sensitivity of the test is generally low in most laboratories, in part because of the lack of antisera directed against other *Legionella* serogroups and species. This method failed to detect the infection in several well-documented pediatric cases. Retrospective diagnosis can be made serologically using the indirect immunofluorescence assay to detect specific antibody production. Seroconversion may not occur for several weeks after onset of infection, and the available serologic assays do not detect all strains of *L. pneumophila* or all species. In view of the low sensitivity of direct detection and the slow growth of the microorganism in culture, the diagnosis of legionellosis should be pursued actively when there is suggestive clinical evidence, including the lack of response to “usual” antibiotics, even when results of other laboratory studies are negative.

Treatment.

Erythromycin (40?mg/kg/24?hr PO or IV), with or without rifampin (15?mg/kg/24?hr), has been empirically established as effective therapy. The newer macrolides including azithromycin (10?mg/kg on day 1, not to exceed 500?mg/day then 5?mg/kg daily for 4 days, PO) and clarithromycin (15?mg/ kg/24?hr PO) and the quinolones (ciprofloxacin, levofloxacin, trovafloxacin, and sparfloxacin) have excellent activity in vitro, although quinolones are not approved for children <18 yr of age. In serious infections or in high-risk patients, parenteral therapy is recommended initially; a switch to oral therapy can be made when a patient has had a clinical response. Acute hearing loss, which is reversible, is associated with high-dose parenteral erythromycin therapy. The duration of therapy for legionnaires' disease is 2–3 wk for erythromycin. Duration of therapy in immunocompetent patients with newer macrolides is 7–10 days. Treatment of extrapulmonary infections, including prosthetic valve endocarditis and sternal wound infections, may require prolonged therapy. Trimethoprim-sulfamethoxazole (TMP-SMZ; 15?mg TMP/kg/24?hr and 75?mg SMZ/kg/24?hr) has been used as an alternative. ß-lactams and aminoglycosides and other antibiotics that do not penetrate mammalian cells are not clinically effective. Relapse (recrudescence) may occur after cessation of erythromycin therapy.

Prognosis.

The mortality rate of community-acquired legionnaires' disease in adults who are hospitalized is approximately 15%. The prognosis depends on underlying host factors and possibly on the duration of the illness before appropriate therapy is begun. Despite appropriate antibiotic therapy, patients may succumb to respiratory complications, such as acute respiratory distress syndrome, associated with artificial ventilation and intubation. A high mortality rate is noted in case reports of premature infants and children, virtually all of whom have been immunocompromised.

Chapter 192 - *Bartonella*

Barbara W. Stechenberg

The spectrum of disease resulting from human infection with *Bartonella* species has expanded rapidly in the past 2 decades, including the association of bacillary angiomatosis with AIDS and cat-scratch disease (CSD) with the fastidious gram-negative rod initially identified as *Rochalimaea henselae*. However, like *Bartonella bacilliformis*, which has been identified for many years, *Rochalimaea* species grow on the surface of eukaryotic host cells and on blood agar. On the basis of these findings, 16S ribosomal RNA gene sequencing, and other molecular genetic homologies, the *Rochalimaea* genus was transferred to the genus *Bartonella*, as part of the alpha subdivision of proteobacteria. Five major *Bartonella* species have been found to be pathogenic for humans: *B. bacilliformis, B. henselae, B. quintana, B. elizabethae*, and most recently *B. clarridgeiae*. Several other *Bartonella* species have been found in animals, particularly rodents and moles (Table 192–1).

Members of the genus *Bartonella* are gram-negative, oxidase-negative, fastidious aerobic rods that ferment no carbohydrates. Only one species, *B. bacilliformis*, is motile by means of polar flagella. Optimal growth is obtained on fresh media containing 5% or more sheep or horse blood in the presence of 5% carbon dioxide. The use of lysis-centrifugation for specimens from blood on chocolate agar for extended periods (2–6 wk) enhances recovery.

192.1 Bartonellosis (*Bartonella bacilliformis*)

The first human *Bartonella* infection described was bartonellosis, a geographically distinct disease caused by *B. bacilliformis*, which causes two predominant forms of illness: **Oroya fever**, a severe, febrile hemolytic anemia; and **verruca peruana (verruga peruana)**, an eruption of hemangioma-like lesions. The organism also causes asymptomatic infection. Bartonellosis is also called **Carrión disease** in honor of the Peruvian medical student who inoculated himself with blood from a verruca and 21 days later developed Oroya fever. He died 39 days after inoculation, thus proving the unitary etiology of the two clinical illnesses.

Etiology.

B. bacilliformis is a small, motile gram-negative organism with a brush of 10 or more

unipolar flagella, which appear to be important components for invasiveness. An obligate aerobe, it grows best at 28°C in semisolid nutrient agar containing rabbit serum and hemoglobin.

Epidemiology.

Bartonellosis is a zoonosis found only in mountain valleys of the Andes Mountains in Peru, Ecuador, Colombia, Chile, and Bolivia at altitudes and environmental conditions favorable for the vector, which is the sandfly, *Lutzomyia verrucarum*.

Pathogenesis.

After the bite, *Bartonella* organisms enter the endothelial cells of blood vessels, where they proliferate. Found throughout the reticuloendothelial system, they then re-enter the bloodstream and parasitize the erythrocytes. They bind on the cells, deform the membranes, and then enter intracellular

TABLE 192.1-1 -- *Bartonella* Causing Human Disease

Disease	Organism	Vector	Primary Risk Factor
Angiomatosis	*B. bacilli formis*	Human body louse	Immunocompromised
Bartonellosis	*B. bacilliformis*	Sandfly (*Lutzomyia verrucarum*)	Living in endemic area (Andes Mountains)
Cat-scratch disease	*B. henselae* *B. clarridgeiae* (1 case)	Cat	Cat scratch or bite
Trench fever	*B. quintana*	Human body louse	Body louse infestation during outbreak
Bacteremia, endocarditis	*B. henselae* *B. quintana* *B. elizabethae*	Cat for *B. henselae*	Severely immunocompromised
Bacillary angiomatosis	*B. henselae* *B. quintana*	Cat for *B. henselae*	Severely immunocompromised
Peliosis hepatis	*B. henselae* *B. quintana*	Cat for *B. henselae*	Severely immunocompromised

vacuoles. The resultant hemolytic anemia may involve as many as 90% of the erythrocytes. Patients who survive this acute phase may or may not develop the cutaneous manifestations, which are nodular hemangiomatous lesions or verrucae ranging in size from a few millimeters to several centimeters.

Clinical Manifestations.

The incubation period is 2–14 wk. Patients may be totally asymptomatic or may have nonspecific symptoms such as headache and malaise without anemia. Patients with Oroya fever are febrile, with rapid development of anemia. Clouding of the sensorium and delirium are common symptoms and may progress to overt psychosis. Physical examination demonstrates signs of severe anemia, icterus, and pallor, which may be associated with generalized lymphadenopathy.

In the pre-eruptive stage, patients may complain of arthralgias, myalgias, and paresthesias. Inflammatory reactions such as phlebitis, pleuritis, erythema nodosum, and encephalitis may develop. The appearance of verrucae is pathognomonic of the eruptive phase. They vary greatly in size and number.

Diagnosis.

The diagnosis is established on clinical grounds in conjunction with a blood smear demonstrating organisms, or by blood culture. The anemia is macrocytic and hypochromic, with reticulocyte counts as high as 50%. *B. bacilliformis* may be seen on Giemsa stain as red-violet rods in the erythrocytes. In the recovery phase, these organisms change to a mere coccoid form and disappear from the blood. In the absence of anemia, the diagnosis depends on blood cultures. In the eruptive phase, the typical verruca confirms the diagnosis. Antibody testing has been used to document infection.

Treatment.

B. bacilliformis is sensitive to many antibiotics, including rifampin, tetracycline, and chloramphenicol. Treatment is very effective in rapidly diminishing fever and eradicating the organism from the blood. Chloramphenicol (50–75?mg/kg/ 24?hr) is considered the drug of choice, because it also is useful in the treatment of concomitant infections such as *Salmonella*. Blood transfusions and supportive care are critical in patients with severe anemia. Treatment for verruca peruana is not necessary unless large lesions are disfiguring or interfere with function; then, surgical excision may be needed. Oral tetracycline, rifampin, or quinolones may aid in healing of lesions.

Prevention.

Prevention depends on avoidance of the vector, particularly at night, by the use of protective clothing and insect repellents (Chapter 285).

192.2 Cat-Scratch Disease (*Bartonella henselae*)

The most common presentation of *Bartonella* infection is CSD, a subacute, regional lymphadenitis caused by *B. henselae*. It is the most common cause of chronic lymphadenitis that persists for >3 wk.

Etiology.

In 1983, small pleomorphic gram-negative bacilli were first visualized by Warthin-Starry stain in affected lymph nodes from patients with CSD. A putative causative organism, *Afipia felis*, was cultured and initially presumed to be the agent of CSD, but most patients with CSD did not develop an immune response to this organism. *A. felis* has not been cultured from lymph node tissue of a patient with CSD. In 1992, *B. henselae* was cultured from the blood of a healthy cat and was used in serologic studies that indicated *B. henselae* as the cause of CSD. Development of serologic tests that showed prevalence of antibodies in 84–100% of cases of CSD, culturing of *B. henselae* from CSD nodes, and detection of *B. henselae* by polymerase chain reaction in the majority of lymph node samples and pus from patients with CSD confirmed the organism as the cause of CSD. Occasional cases of CSD may be caused by other organisms; one report described a veterinarian with CSD caused by *B. clarridgeiae*.

Epidemiology.

CSD is common, with more than 24,000 estimated cases per year in the United States. It is transmitted by cutaneous inoculation. Most (87–99%) patients have had contact with cats, many of which are kittens younger than 6 mo. More than 50% have a definite history of a cat scratch or bite. Cats have a high-level *Bartonella* bacteremia for months without any clinical symptoms; kittens are more frequently bacteremic than adult cats. The precise mechanism of cat-to-human transmission remains unclear. Transmission between cats is arthropod-borne by the cat flea, *Ctenocephalides felis*. In temperate zones, the majority of cases occur between September and March. This may be related to the seasonal breeding of domestic cats or to close proximity to family pets in the fall and winter. In tropical zones, there is no seasonal prevalence. Distribution is worldwide and infection occurs in all races.

Cat scratches appear to be more common among children, and boys are affected more often than girls. CSD is a sporadic illness; only one family member usually is affected, even though many siblings play with the same kitten. However, clusters do occur with family cases within weeks of one another. Anecdotal reports have implicated other sources such as dog scratches, wood splinters, fishhooks, cactus spines, and porcupine quills.

Pathogenesis.

The pathologic findings in the primary inoculation papule and affected lymph nodes are similar. Both show a central avascular necrotic area with surrounding lymphocytes, giant cells, and histiocytes. Three stages of involvement occur in affected nodes, although they may coexist in the same node. First is generalized enlargement with thickening of the cortex and germinal center hypertrophy. Lymphocytes predominate. Epithelioid granulomas with Langhans' giant cells are scattered throughout the node. In the middle stage, granulomas become

denser, fuse, and become infiltrated with polymorphonuclear leukocytes. Central necrosis of these granulomas begins in this stage, progressing to the last stage with formation of large pus-filled sinuses. This purulent material may rupture into surrounding tissue. Similar granulomas have been found in the liver and osteolytic lesions of bone when those organs are involved.

Clinical Manifestations.

After an incubation period of 7–12 days (range 3–30 days), one or more 3–5?mm red papules develop at the site of cutaneous inoculation, often reflecting a linear cat scratch. Because of their small size, these lesions are often overlooked but with careful search are found in at least two thirds of patients. Lymphadenopathy generally is evident within a period of 1–4 wk. Chronic regional lymphadenitis is the hallmark, affecting the first or second set of nodes draining the entry site. Affected lymph nodes in order of frequency include the axillary, cervical, submandibular, preauricular, epitrochlear, femoral, and inguinal nodes. Involvement of more than one group occurs in 10–20% of patients, although at a given site, half the cases involve several nodes.

Nodes involved are usually tender and have overlying erythema but without cellulitis. They usually range between 1–5?cm in size, although they can become much larger. Between 10–40% eventually suppurate. The duration of enlargement is usually 1–2 mo, with persistence up to 1 yr in rare cases. Fever, usually a temperature of 38–39℃, occurs in about 30% of patients. Other nonspecific symptoms including malaise, anorexia, fatigue, and headache affect less than one third of patients. Transient rashes may occur in about 5% of patients. These consist mainly of truncal maculopapular rashes; erythema nodosum, erythema multiforme and erythema annulare are also reported.

The most common atypical presentation, noted in 2–17% of patients, is **Parinaud occuloglandular syndrome**, which is unilateral conjunctivitis followed by preauricular lymphadenopathy. Direct eye inoculation as a result of rubbing with the hands after cat contact is the presumed mode of spread. A conjunctival granuloma may be found at the inoculation site. The involved eye is usually not painful and has little or no discharge, but it may be quite red and swollen. Submandibular or cervical lymphadenopathy may also occur. CSD is usually a self-limited infection with spontaneous resolution within a few weeks to months.

More severe, disseminated illness occurs in a small percentage of patients. These patients present with high fever often persisting for several weeks. Although systemic symptoms are usually more pronounced than with isolated lymphadenitis, they often seem mild relative to fever, the exception being abdominal pain and weight loss, both of which can be dramatic. Hepatosplenomegaly may occur, although hepatic dysfunction is rare. Granulomatous changes may be seen in the liver and spleen. Another common site of dissemination is bone, with the development of granulomatous osteolytic lesions. These are usually associated with localized pain, without erythema, tenderness, or swelling.

Diagnosis.

In most cases, the diagnosis can be strongly suspected on clinical grounds with the history of exposure to a cat. Several serologic assays have been developed. The Centers for Disease Control and Prevention has developed an indirect immunofluorescent assay (IFA) that has shown good correlation with disease. Other IFA and enzyme-linked immunoassay tests are commercially available, although little comparative data are available. Most patients have elevated antibody titers at presentation; however, the timing of IgG and IgM response to *B. henselae* can be quite variable. There is cross reactivity among *Bartonella* species, particularly *B. henselae* and *B. quintana*.

If tissue specimens are obtained, bacilli may be visualized with Warthin-Starry and Brown-Hopp tissue Gram stains. *Bartonella* DNA can be identified by polymerase chain reaction, but this test is not available in most hospitals. Culturing of the organism is not practical for clinical diagnosis.

Use of a skin test antigen prepared by heat-treating purulent aspirate from a CSD node is strongly discouraged because of lack of standardization and potential transmission of infectious agents.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis of CSD includes virtually all causes of lymphadenopathy (Chapter 482). The more common entities include pyogenic lymphadenitis primarily from staphylococcal or streptococcal infections, atypical mycobacterial infections, and malignancy. Less common entities include tularemia, brucellosis, or sporotrichosis. Epstein-Barr virus, cytomegalovirus, or *Toxoplasma gondii* infections usually cause more generalized lymphadenopathy.

Laboratory Findings.

Routine laboratory tests are not helpful. The erythrocyte sedimentation rate is often elevated. The white blood cell count may be normal or mildly elevated. Hepatic transaminases may be elevated in systemic disease. Ultrasonography or CT may reveal many granulomatous nodules in the liver and spleen, appearing as hypodense round irregular lesions.

Treatment.

Antibiotic treatment of CSD is not clearly beneficial. For most patients, treatment consists of conservative symptomatic care and observation. Studies show a significant discordance between in vitro activity of antibiotics and clinical effectiveness. For many patients, diagnosis is considered in the context of failure to respond to ß-lactam antibiotic treatment of presumed staphylococcal lymphadenitis. Azithromycin, clarithromycin, trimethoprim-sulfamethoxazole, rifampin, ciprofloxacin, and gentamicin appear to be the best agents if treatment is considered. A small prospective study of oral azithromycin (500?mg on day 1, then 250?mg on days 2–5; for smaller children, 10?mg/kg/24?hr on day 1 and 5?mg/kg/24?hr day 2–5) showed a decrease in initial lymph node volume in 50% of patients during the first 30 days, but after 30 days there was no difference in lymph node volume. No other clinical benefit was found. It is clear that for the majority of patients, the disease is self-limited, with resolution occurring over weeks to months, and that treatment affords minimal, if any, clinical benefit.

Suppurative lymph nodes that become tense and extremely painful should be drained by needle aspiration, which may need to be repeated. Incision and drainage of nonsuppurative nodes should be avoided because chronic draining sinuses may result. Surgical excision of the node rarely is necessary.

Complications.

Encephalopathy can occur in as many as 5% of patients, typically occurring 1–3 wk after the onset of lymphadenitis with the sudden onset of neurologic symptoms, which often include seizures, combative or bizarre behavior, and altered level of consciousness. Imaging studies are generally normal. The cerebrospinal fluid is normal or shows minimal pleocytosis and protein elevation. Recovery occurs without sequelae in nearly all patients but takes place slowly over many months.

Other neurologic manifestations include peripheral facial nerve paralysis, myelitis, radiculitis, compression neuropathy, and cerebellar ataxia. One patient with encephalopathy with persistent cognitive impairment and memory loss has been reported.

Stellate macular retinopathy has been associated with several infections, including CSD. Children and young adults present with unilateral or rarely bilateral loss of vision with central scotoma, optic disc swelling, and macular star formation from exudates radiating out from the macula. The findings resolve completely, with recovery of vision, usually within 2–3 mo.

Hematologic manifestations include hemolytic anemia, thrombocytopenic purpura, nonthrombocytopenic purpura, and eosinophilia. Leukocytoclastic vasculitis similar to Henoch-Schönlein purpura has been reported in association with CSD in one child. A systemic presentation of CSD with pleurisy, arthralgia or arthritis, mediastinal masses, enlarged nodes at the head of the pancreas, and atypical pneumonia has also been reported.

Prognosis.

The prognosis for CSD in a normal host is generally excellent, with resolution of clinical findings over several months. Recovery occasionally is slower and may take as long as a year.

Prevention.

Person-to-person spread of *Bartonella* infections is not known. Isolation is not

necessary. Prevention would require elimination of cats from households, which is not practical or necessarily desirable. Awareness of the risk of cat (and particularly kitten) scratches should be emphasized to parents.

192.3 Trench Fever (*Bartonella quintana*)

Etiology.

The causative agent of trench fever was first designated as *Rickettsia quintana*, then assigned to the genus *Rochalimaea*, which has been reassigned as *B. quintana*.

Epidemiology.

Trench fever was first recognized as a distinct clinical entity during World War I, when more than a million troops in the trenches were infected. The disease became quiescent until World War II, when it again was epidemic. It is extremely rare in the United States.

Humans are the only known reservoir. No other animal is naturally infected, nor are the usual laboratory animals susceptible. The human body louse, *Pediculus humanus* var. *corporis*, is the vector, capable of transmission to a new host 5–6 days after feeding on an infected person. Lice excrete the organism for life; transovarian passage does not occur. Humans may have prolonged asymptomatic bacteremia for years.

Clinical Manifestations.

The incubation period averages about 22 days (range, 4–35 days). The clinical presentation is highly variable. Symptoms can be very mild and brief. About half of infected persons have a single febrile illness with abrupt onset lasting 3–6 days. In others, prolonged, sustained fever may occur. More commonly, patients have periodic febrile illness with three to eight episodes lasting 4–5 days each, sometimes occurring over a period of a year or more. This form is reminiscent of malaria or relapsing fever *(Borrelia recurrentis)*. Afebrile bacteremia can occur.

Clinical findings usually include fever (usually temperature of 38.5–40℃), malaise, chills, sweats, anorexia, and severe headache. Common findings include marked conjunctival injection, tachycardia, myalgias, arthralgias, and severe pain in the neck, back, and legs. Crops of erythematous macules or papules may occur or the trunk in as many as 80% of patients. Splenomegaly and mild liver enlargement may be noted.

Diagnosis.

In nonepidemic situations, it is impossible to establish a diagnosis of trench fever on clinical grounds because the findings are not distinctive. A history of body louse infection or having been in an area of epidemic disease should heighten suspicions. *B. quintana* can be cultured from the blood with modification to include culture on epithelial cells. Serologic tests for *B. quintana* are available, but there is cross reaction with *B. henselae*.

Treatment.

There are no controlled trials of treatment; however, patients with trench fever have responded dramatically to tetracycline and chloramphenicol with rapid defervescence.

192.4 Bacillary Angiomatosis and Bacillary Peliosis Hepatis (*Bartonella henselae* and *Bartonella quintana*)

Both *B. henselae* and *B. quintana* cause two vascular proliferative diseases, bacillary angiomatosis and bacillary peliosis, in severely immunocompromised persons, primarily adult patients with AIDS or cancer and organ transplant recipients. Subcutaneous and lytic bone lesions are strongly associated with *B. quintana*, whereas peliosis hepatis is associated exclusively with *B. henselae*.

Bacillary Angiomatosis.

Lesions of cutaneous bacillary angiomatosis (BA), also known as epithelioid angiomatosis, are the most easily identified and recognized form of *Bartonella* infection in immunocompromised hosts. They are found primarily in patients with AIDS with very low CD4 counts. The clinical appearance can be quite diverse. The vasoproliferative lesions of BA may be cutaneous or subcutaneous and resemble the vascular lesions (verruca peruana) of *B. bacilliformis* in immunocompetent persons. They are erythematous papules on an erythematous base with a collarette of scale. They may enlarge to form large pedunculated lesions. Ulceration may occur, as can profuse bleeding after trauma.

BA may be clinically indistinguishable from Kaposi sarcoma. Other considerations in the differential diagnosis are pyogenic granuloma and verruca peruana *(B. bacilliformis).* Deep soft tissue masses caused by BA may mimic a malignancy.

Osseous BA lesions commonly involve the long bones. These lytic lesions are very painful and highly vascular. Occasionally found is an erythematous plaque over the lesion. The high degree of vascularity, which produces a very positive result on a technetium-99m methylene diphosphonate bone scan, resembles a malignant lesion.

Lesions can be found in virtually any organ, producing similar vascular proliferative lesions. They may appear raised, nodular, or ulcerative when seen on endoscopy or bronchoscopy. They may be associated with enlarged lymph nodes with or without an obvious local cutaneous lesion. Lesions in one brain parenchyma have been described.

Bacillary Peliosis.

Bacillary peliosis affects the reticuloendothelial system, primarily the liver (**peliosis hepatis**) and less frequently the spleen and lymph nodes. It is a vasoproliferative disorder characterized by random proliferation of venous lakes surrounded by fibromyxoid stroma harboring numerous bacillary organisms. Clinical findings include

fever and abdominal pain in association with abnormal results of liver function tests, particularly a markedly increased alkaline phosphatase level. Cutaneous BA or splenomegaly may be associated, with or without thrombocytopenia or pancytopenia. The vascular proliferative lesions in the liver and spleen appear on CT scan as hypodense lesions scattered throughout the parenchyma. The differential diagnosis includes hepatic Kaposi sarcoma, lymphoma, and disseminated infection with *Pneumocystis carinii* or *Mycobacterium avium* complex.

Bacteremia and Endocarditis.

B. henselae, *B. quintana*, and *B. elizabethae* all have been reported to cause bacteremia or endocarditis. They are associated with symptoms of prolonged fevers, night sweats, and profound weight loss. A cluster of cases in Seattle in 1993 occurred in a homeless population with chronic alcoholism. These patients with high fever or hypothermia were thought to represent “urban trench fever,” but no body louse infestation was associated. Some cases of culture-negative endocarditis may represent *Bartonella* endocarditis. One report described central nervous system involvement with *B. quintana* in two children.

Diagnosis.

Diagnosis of BA is made initially by biopsy. The characteristic small vessel proliferation with mixed inflammatory response and the staining of bacilli by Warthin-Starry silver staining distinguish it from Kaposi sarcoma or pyogenic granuloma. Travel history can usually preclude verruca peruana.

Culture is impractical for CSD but is the diagnostic procedure for suspected bacteremia or endocarditis. The use of lysis-centrifugation technique or fresh chocolate or heart infusion agar with 5% rabbit blood with prolonged incubation may increase the yield of culture.

Treatment.

Bartonella infections in immunocompromised hosts caused by both *B. henselae* and *B. quintana* have been treated

successfully with antimicrobial agents. Rigorous studies have not been published; thus, therapy is guided by clinical experience. BA responds rapidly to erythromycin, azithromycin or clarithromycin, which are the drugs of choice. An alternative choice is doxycycline or tetracycline. Severely ill patients with peliosis hepatis, endocarditis, or osteomyelitis may be treated initially with intravenous erythromycin or doxycycline with the addition of rifampin or gentamicin. A Jarisch-Herxheimer reaction may occur. Relapses may follow; prolonged treatment for several months may be necessary.

Prevention.

Immunocompromised persons should consider the potential risks of cat ownership because of the risks of *Bartonella* infections, as well as toxoplasmosis and enteric infections. Those who elect to obtain a cat should adopt or purchase a cat >1 yr of age and in good health.

Section 4 - *Anaerobic Bacterial Infections*

Chapter 193 - Botulism (*Clostridium botulinum*)*

Robert Schechter
Stephen S. Arnon

Three naturally occurring forms of human botulism are known: infant botulism (the most common in the United States), foodborne (classic) botulism, and wound botulism. A fourth, manmade form, inhalational botulism, is one possible outcome of a bioterrorist attack.

Etiology.

Botulism is the acute, flaccid paralysis caused by the neurotoxin produced by *Clostridium botulinum* or, rarely, an equivalent neurotoxin produced by atypical strains of *C. butyricum* and *C. baratii*. *C. botulinum* is a gram-positive, spore-forming obligate anaerobe whose natural habitat worldwide is soil, dust, and marine sediments. It is found in a wide variety of fresh and cooked agricultural products. Spores of some *C. botulinum* strains endure boiling for several hours, which enables the organism to survive efforts at food preservation. In contrast, botulinum toxin is heat labile and easily destroyed by heating at =85°C for 5?min. Neurotoxigenic *C. butyricum* has been isolated from a soybean food and from soils near Lake Weishan in China, the site of foodborne botulism outbreaks associated with this organism. Little is known about the ecology of neurotoxigenic *C. baratii*.

Botulinum toxin is the most poisonous substance known, the parenteral human lethal dose being estimated at 10^{-6} mg/kg. The toxin blocks neuromuscular transmission and causes death through airway and respiratory muscle paralysis. Seven antigenic toxin types, assigned the letters A–G, are distinguished by the inability of neutralizing antibody against one toxin type to protect against a different toxin type. The seven toxin types serve as convenient clinical and epidemiologic markers. Toxin types A, B, E, and F are well-established causes of human botulism, whereas types C and D cause illness in other animals. Neurotoxigenic *C. butyricum* strains produce a type E toxin, whereas neurotoxigenic *C. baratii* strains produce a type F toxin. Type G has not been established as a cause of either human or animal disease.

Botulinum toxin is a simple di-chain protein consisting of a 100-kd "heavy" chain that contains the neuronal attachment sites and a 50-kd "light" chain that is taken into the cell after binding. The phenomenal potency of botulinum toxin is explained by the fact that its seven light chains are zinc-endopeptidases, whose substrates are one or two of three proteins of the docking complex by which synaptic vesicles fuse with the terminal cell membrane and release acetylcholine into the synaptic cleft.

Epidemiology.

Infant botulism has been reported from all inhabited continents except Africa. Notably, the infant is the only family member who is ill. The most striking epidemiologic feature of infant botulism is its age distribution, in which in 95% of cases, the infants are between 3 wk and 6 mo of age, with a broad peak at 2–4 mo of age. This pattern is matched only by one other condition, the sudden infant death syndrome. However, cases in infants as young as 3 days or as old as 382 days at onset have been recognized. The male:female ratio of cases is essentially 1:1, and cases have occurred in most racial and ethnic groups.

Infant botulism is an uncommon and often unrecognized illness. In the United States, about 100 cases are diagnosed annually; more than 1,800 cases were reported from 1976 to 2000. Approximately 40% of U.S. cases were reported from California.

*All material in this chapter is in the public domain, with the exception of any borrowed figures or tables.

Consistent with the known asymmetric soil distribution of *C. botulinum* toxin types, most cases west of the Mississippi River have been caused by type A strains, and most cases east of the Mississippi River have been caused by type B strains. One case each in the states of New Mexico, Washington, and Ohio resulted from *C. baratii* and type F toxin, whereas cases in Italy resulted from *C. butyricum* and type E toxin. Identified risk factors for the illness include the ingestion of honey and a slow intestinal transit time (<1 stool/day). Breast-feeding appears to provide protection against fulminant, sudden death from infant botulism. Under rare circumstances of altered intestinal anatomy, physiology, and microflora, older children and adults may contract infant-type botulism.

Foodborne botulism results from the ingestion of a food in which *C. botulinum* has multiplied and produced its toxin. Recent outbreaks in North America associated with baked potatoes, sautéed onions, and chopped garlic served in restaurants have revised the traditional view of foodborne botulism as resulting mainly from home-canned foods. Other outbreaks in the United States have occurred from commercial foods sealed in plastic pouches that relied solely on refrigeration to prevent outgrowth of *C. botulinum* spores. Noncanned foods responsible for recent foodborne botulism episodes include peyote tea, the hazelnut flavoring added to yogurt, sweet cream cheese, sautéed onions in "patty melt" sandwiches, potato salad, and fresh and dried fish. A recent trend toward a single case per outbreak or

of cases presenting separately in different cities or hospitals has meant that the physician cannot rely on the temporal and geographic clustering of illness to suggest the diagnosis.

Most preserved foods have been implicated in foodborne botulism, but the usual offenders in the United States are the “low-acid” (pH = 6.0) home-canned foods such as jalapeño peppers, asparagus, olives, and beans. The potential for foodborne botulism exists throughout the world, but outbreaks occur most commonly in the temperate zones rather than the tropics, where preservation of fruits, vegetables, and other foods is less common.

In the past 10 yr, approximately nine outbreaks and 24 cases of foodborne botulism have occurred annually in the United States. Most of the continental U.S. outbreaks resulted from proteolytic type A or type B strains, which produce a strongly putrefactive odor in the food that some people find necessary to verify by tasting. In contrast, in Alaska and Canada, most foodborne outbreaks have resulted from nonproteolytic type E strains in Native American foods, such as fermented salmon eggs and seal flippers, which do not exhibit signs of spoilage. A further hazard of type E strains is their ability to grow at the temperatures (5℃) maintained by household refrigerators.

Wound botulism is an exceptionally rare disease, with less than 300 cases reported worldwide, but it is important to pediatrics because adolescents and children are disproportionately affected. Although many cases have occurred in young, physically active males at greatest risk of traumatic injury, wound botulism also occurs with crush injuries in which no break in the skin is evident. In the past 10 yr, wound botulism from injection has become increasingly common in adult heroin abusers in the western United States, not always with evident abscess formation or cellulitis.

A single outbreak of inhalational botulism was reported in 1962 in which three laboratory workers in Germany were exposed unintentionally to aerosolized botulinum toxin.

Pathogenesis.

All forms of botulism produce disease through a final common pathway. Botulinum toxin is carried by the bloodstream to peripheral cholinergic synapses, where it binds irreversibly, blocking acetylcholine release and causing impaired neuromuscular and autonomic transmission. Infant botulism is an infectious disease that results from ingesting the spores of any of the three botulinum toxin-producing clostridial strains, with subsequent spore germination, multiplication, and production of botulinum toxin in the large intestine. Foodborne botulism is an intoxication that results when preformed botulinum toxin contained in an improperly preserved or inadequately cooked food is swallowed. Wound botulism results from spore germination and colonization of traumatized tissue by *C. botulinum*; it is the analog of tetanus. Inhalational botulism occurs when aerosolized botulinum toxin is inhaled. A bioterrorist attack could result in large or small outbreaks of inhalational or foodborne botulism (Chapter 706).

Because botulinum toxin is not a cytotoxin, it causes no overt macroscopic or microscopic pathology. However, secondary pathologic changes (e.g., pneumonia, petechiae on intrathoracic organs) may be found at autopsy. No diagnostic technique is available to identify botulinum toxin bound at the neuromuscular junction. The healing process in botulism consists of sprouting of new terminal unmyelinated motor neurons. Movement resumes when these new twigs locate noncontracting muscle fibers and reinnervate them by inducing formation of a new motor end plate. In experimental animals, this process takes about 4 wk.

Clinical Manifestations.

Botulinum toxin is distributed hematogenously. Because relative blood flow and density of innervation are greatest in the bulbar musculature, all forms of botulism manifest neurologically as a symmetric, descending, flaccid paralysis beginning with the cranial nerve musculature. It is not possible to have botulism without having multiple bulbar palsies, yet in infants such symptoms as poor feeding, weak suck, feeble cry, drooling, and even obstructive apnea are often not recognized as bulbar in origin. Patients with evolving illness may already have generalized weakness and hypotonia in addition to bulbar palsies when first examined. In contrast to botulism caused by *C. botulinum*, a majority of the rare cases caused by intestinal colonization with *C. butyricum* have had a Meckel diverticulum along with abdominal distention, often leading to misdiagnosis as an acute abdomen.

In older children with foodborne or wound botulism, the onset of neurologic symptoms follows a characteristic pattern of diplopia, blurred vision, ptosis, dry mouth, dysphagia, dysphonia, and dysarthria, with deceased gag and corneal reflexes. Importantly, because the toxin acts only on motor nerves, paresthesias are not seen in botulism, except when a patient hyperventilates from anxiety. The sensorium remains clear, but this may be difficult to ascertain because of the slurred speech.

Foodborne botulism begins with gastrointestinal symptoms of nausea, vomiting, or diarrhea in about one third of cases. These symptoms are thought to result from metabolic by-products of growth of *C. botulinum* or from the presence of other toxic contaminants in the food, because gastrointestinal distress is rarely observed in wound botulism. Constipation may occur in foodborne botulism once flaccid paralysis becomes evident. Illness usually begins 12–36?hr after ingestion of the contaminated food but can range from as little as 2?hr to as long as 8 days. The incubation period in wound botulism is 4–14 days. Fever may be present in wound botulism but is absent in foodborne botulism unless a secondary infection (e.g., pneumonia) is present. All forms of botulism display a wide spectrum in their clinical severity, from the very mild with minimal ptosis, flattened facial expression, minor dysphagia, and dysphonia to the fulminant, with rapid onset of extensive paralysis, frank apnea, and fixed, dilated pupils. Fatigability with repetitive muscle activity is the clinical hallmark of botulism.

Infant botulism differs in apparent initial symptoms of illness only because the infant cannot verbalize them. Usually, the first indication of illness is a decreased frequency or even absence of defecation, although this sign is frequently overlooked. Parents typically notice inability to feed, lethargy, listlessness, weak cry, and diminished spontaneous movement. Dysphagia may be

evident as secretions drooling from the mouth. Gag, suck, and corneal reflexes diminish as the paralysis advances. Oculomotor palsies may be evident only with sustained observation. Paradoxically, the pupillary light reflex may be unaffected until the child is severely paralyzed, or it may be initially sluggish. Loss of head control is typically a prominent sign. Respiratory arrest may occur suddenly from airway occlusion by unswallowed secretions or from obstructive flaccid pharyngeal musculature. Occasionally, the diagnosis of infant botulism is suggested by a respiratory arrest that occurs after the infant is curled into position for lumbar puncture.

In mild cases or in the early stages of illness, the physical signs of infant botulism may be subtle and easily missed. Eliciting cranial nerve palsies and fatigability of muscular function requires careful examination. Ptosis may not be seen unless the head of the child is kept erect.

Diagnosis.

Clinical diagnosis of botulism is confirmed by specialized laboratory testing that often requires days to complete. Therefore, clinical diagnosis is the foundation for early recognition of and response to all forms of botulism. Routine laboratory studies, including those of the cerebrospinal fluid (CSF), are normal in botulism unless dehydration, starvation (metabolic acidosis and ketosis), or secondary infection is present.

The classic picture of botulism is the acute onset of a symmetric flaccid descending paralysis with clear sensorium, no fever, and no paresthesias. *Suspected botulism represents a medical and public health emergency that is immediately reportable by telephone in most U.S. health jurisdictions.* State health departments (first call) and the Centers for Disease Control and Prevention (second call; 404-639-2206 workdays; 404-639-2888 at other times) can arrange for diagnostic testing, epidemiologic investigation, and provision of equine antitoxin.

The diagnosis of botulism is unequivocally established by demonstrating the presence of botulinum toxin in serum or of *C. botulinum* toxin or organisms in wound material or feces. *C. botulinum* is not part of the normal resident intestinal flora of humans, and its presence in the setting of acute flaccid paralysis is diagnostic. An epidemiologic diagnosis of foodborne botulism can be established when *C. botulinum* organisms and toxin are found in food eaten by patients.

Electromyography (EMG) can sometimes distinguish between causes of acute flaccid paralysis, although results may be variable, including normal, in patients with botulism. The distinctive EMG finding in botulism is facilitation (potentiation) of the evoked muscle action potential at high-frequency (50?Hz) stimulation. In infant botulism, a characteristic pattern, known by the acronym BSAP (brief, small, abundant motor-unit action potentials), is present only in clinically weak muscles. Nerve conduction velocity and sensory nerve function are normal in botulism.

Infant botulism requires a high index of suspicion for early diagnosis (Box 193–1). Even today, more than 25 yr after its recognition, “rule-out sepsis” is the most common admission diagnosis. If a previously healthy infant, usually 2–4 mo of age, develops weakness with difficulty in sucking, swallowing, crying, or breathing, infant botulism should be considered a likely diagnosis. A careful cranial nerve examination is then helpful.

DIFFERENTIAL DIAGNOSIS.

Botulism is frequently misdiagnosed, most often as a polyradiculoneuropathy (Guillain-Barré or Miller Fisher syndrome), myasthenia gravis, or a disease of the central nervous system (Box 193–2). In the United States, botulism is more likely than Guillain-Barré syndrome, intoxication, or poliomyelitis to cause a cluster of cases of acute flaccid paralysis. Botulism differs from other flaccid paralyses in its prominent cranial nerve palsies disproportionate to milder weakness and hypotonia below the neck, in its symmetry, and in its absence of sensory nerve damage.

Additional diagnostic procedures may be useful in rapidly excluding botulism as the cause of paralysis. Cerebrospinal fluid

Box 193-1. Differential Diagnosis of Infant Botulism

ADMISSION DIAGNOSIS	COMMON SUBSEQUENT DIAGNOSES
Suspected sepsis	Guillain-Barré syndrome
Pneumonia	Myasthenia gravis
Dehydration	Disorders of amino acid metabolism
Viral syndrome	Hypothyroidism
Hypotonia of unknown etiology	Drug ingestion
	Brainstem encephalitis
Constipation	Heavy metal poisoning (Pb, Mg, As)
Failure to thrive	Poliomyelitis
Werdnig-Hoffmann disease	Viral polyneuritis
	Hirschsprung disease

Werdnig-Hoffmann disease	
	Hirschsprung disease
	Metabolic encephalopathy
	Medium chain acetyl-CoA dehydrogenase (MCAD) deficiency

Box 193-2. Differential Diagnosis of Foodborne and Wound Botulism

Acute gastroenteritis	Aminoglycoside-associated paralysis
Myasthenia gravis	Tick paralysis
Guillain-Barré syndrome	Hypocalcemia
Organophosphate poisoning	Hypermagnesemia
Meningitis	Carbon monoxide poisoning
Encephalitis	Hyperemesis gravidarum
Psychiatric illness	Laryngeal trauma
Cerebrovascular accident	Diabetic complications
Poliomyelitis	Inflammatory myopathy
Hypothyroidism	Overexertion

(CSF) is unchanged in botulism but is abnormal in many central nervous system diseases. Although the CSF protein level eventually is elevated in Guillain-Barré syndrome, it may be normal early in illness. Imaging of the brain, spine, and chest may reveal hemorrhage, inflammation, or neoplasm. A test dose of edrophonium chloride briefly reverses paralytic symptoms in many patients with myasthenia gravis and, reportedly, in some with botulism. A close inspection of the skin, especially the scalp, may reveal an attached tick that is causing paralysis. Possible organophosphate intoxication should be pursued aggressively because specific antidotes (oximes) are available and because the patient may be part of a commonly exposed group, some of whom have yet to develop illness. Other tests that require days for results include stool culture for *Campylobacter jejuni* as a precipitant of Guillain-Barré syndrome and assays for the autoantibodies that cause myasthenia gravis, Lambert-Eaton syndrome, and Guillain-Barré syndrome.

Treatment.

Management of botulism rests on three principles: (1) fatigability with repetitive muscle activity is the clinical hallmark of the disease; (2) complications are best avoided by anticipating them; and (3) meticulous supportive care is a necessity. The first principle applies mainly to feeding and breathing. Correct positioning is imperative to protect the airway and improve respiratory mechanics. The patient is placed face up on a rigid-bottomed crib (or bed), the head of which is tilted at 30 degrees. A small cloth roll is placed under the cervical vertebrae to tilt the head back so that secretions drain to the posterior pharynx and away from the airway. In this tilted position the abdominal viscera pull the diaphragm down, thereby improving respiratory mechanics. The patient's head and torso should not be elevated by bending the middle of the bed; if this is done, the hypotonic thorax will slump into the abdomen and breathing will be compromised.

About one half of patients require endotracheal intubation, which is best done prophylactically. The indications include diminished gag and cough reflexes and progressive airway obstruction by secretions. With meticulous management technique (especially

proper tube diameter), monitoring, and positioning, patients have tolerated months of intubation without subglottic stenosis or need for tracheostomy.

Feeding should be done by a nasogastric or nasojejunal tube until sufficient oropharyngeal strength and coordination enables feeding by breast or bottle. Expressed breast milk is the most desirable food for infants, in part because of its immunologic components (e.g., sIgA, lactoferrin, leukocytes). Tube feeding also assists in the restoration of peristalsis, a nonspecific but probably essential part of eliminating *C. botulinum* from the intestinal flora. Intravenous feeding (hyperalimentation) is discouraged because of the potential for infection and the advantages to tube feeding.

Antibiotic therapy is not part of the treatment of uncomplicated infant or foodborne botulism because the toxin is primarily an intracellular molecule that is released into the intestinal lumen with vegetative bacterial cell death and lysis. Antibiotics are reserved for the treatment of secondary infections, and in the absence of antibody therapy a nonclostridiocidal antibiotic such as trimethoprim-sulfamethoxazole is preferred. Aminoglycoside antibiotics should be avoided because they may potentiate the blocking action of botulinum toxin at the neuromuscular junction. However, wound botulism requires aggressive treatment with antibiotics and antitoxin in a manner analogous to tetanus (Chapter 194). The currently licensed botulinum antitoxin used in foodborne and wound botulism is a horse serum–derived product that has side effects of serum sickness, anaphylaxis, and potential lifelong

sensitization to equine proteins; its use in children requires careful consideration.

Specific treatment for infant botulism is now available. In California a 5-year, randomized, double-blind, placebo-controlled treatment trial demonstrated the apparent safety and efficacy of **human-derived botulinum antitoxin** (BIG-IV), formally known as botulism immunoglobulin intravenous (human). Use of BIG-IV reduced mean hospital stay from approximately 5.5 wk to approximately 2.5 wk and reduced mean hospitalization cost by approximately $70,000 per case. Treatment with BIG-IV should be started as early in the illness as possible. In the United States, BIG-IV may be obtained from the California Department of Health Services (24-hour telephone: 510-540-2646; http://www.infantbot.org). Older patients with suspected food, wound, or inhalational botulism may be treated with equine botulinum antitoxin, available in the United States through the Centers for Disease Control and Prevention by way of state and local health departments.

Because sensation remains intact, providing auditory, tactile, and visual stimuli is beneficial. Maintaining strong central respiratory drive is essential, so sedatives or central nervous system depressants (e.g., metoclopramide) are discouraged. Full hydration and stool softeners such as lactulose may mitigate the protracted constipation. Cathartics are not recommended. Patients with foodborne and infant botulism excrete *C. botulinum* toxin and organisms in their feces, often for weeks, and care should be taken in handling their excreta. When bladder palsy occurs in severe cases, gentle suprapubic pressure with the patient in the sitting position with the head supported may help attain complete voiding and reduce the risk of urinary tract infection. Families may require emotional and financial support, especially when the paralysis of botulism is prolonged.

Complications.

Avoidance of complications is best accomplished by noting past experience (Box 193–3); all of these complications are nosocomial, and some are iatrogenic. Even so, some critically ill, paralyzed patients who must spend weeks or months on ventilators in intensive care units will inevitably develop complications. Suspected “relapses” in infant botulism usually reflect premature hospital discharge, an undiscovered underlying complication, such as pneumonia, or perhaps additional toxemia.

Box 193-3. Complications of Infant Botulism

- Adult respiratory distress syndrome
- Aspiration
- *Clostridium difficile* enterocolitis
- Fracture of the femur
- Inappropriate antidiuretic hormone secretion
- Misplaced or plugged endotracheal tube
- Otitis media
- Pneumonia
- Recurrent atelectasis
- Seizures secondary to hyponatremia
- Sepsis
- Subglottic stenosis
- Tension pneumothorax
- Transfusion reaction
- Tracheal granuloma
- Tracheitis
- Urinary tract infection

Prognosis.

When the regenerating nerve endings have induced formation of a new motor end plate, neuromuscular transmission is restored. In the absence of complications, particularly those related to hypoxia, the prognosis in infant botulism is for full and complete recovery. Hospital stay in untreated infant botulism averages approximately 1 mo but differs significantly by toxin type, with untreated type B patients being hospitalized a mean of 3.7 wk and untreated type A patients 5.6 wk. In the United States, the case-fatality ratio for hospitalized infant botulism is <1%. The case-fatality

ratio in foodborne and wound botulism varies by age, with younger patients having the best prognosis. Some adults with botulism have reported chronic weakness and fatigue as sequelae. After recovery, untreated infant botulism patients appear to have an increased incidence of strabismus that requires timely screening and treatment.

Prevention.

Foodborne botulism is best prevented by adhering to safe methods of home canning (pressure cooker and acidification), by avoiding suspicious foods, and by heating all home canned foods to 85°C for =5?min. Wound botulism is best prevented by not using illicit drugs and by treatment of contaminated wounds with thorough cleansing, surgical debridement, and provision of appropriate antibiotics.

Most infant botulism patients probably inhale and then swallow airborne clostridial spores; these cases cannot be prevented. The one identified, avoidable source of botulinum spores for infants is honey. Honey is an unsafe food for any child younger than 1 yr of age. Corn syrups were once thought to be a possible source of botulinum spores, but recent evidence indicates otherwise. Breast-feeding appears to slow the onset of infant botulism and to diminish the risk of sudden death in infants in whom the disease develops.

Chapter 194 - Tetanus (*Clostridium tetani*)

Stephen S. Arnon

Etiology.

Tetanus, historically called **lockjaw**, is an acute, spastic paralytic illness caused by tetanus toxin, the neurotoxin produced by *Clostridium tetani*, a motile, gram-positive, spore-forming obligate anaerobe whose natural habitat worldwide is soil, dust, and the alimentary tracts of various animals. It forms spores terminally, thus producing a drumstick or tennis racket appearance microscopically. Tetanus spores can survive boiling but not autoclaving, whereas the vegetative cells are killed by antibiotics, heat, and standard disinfectants. Unlike many clostridia, *C. tetani* is not a tissue-invasive organism; instead it causes illness through the effects of a single toxin, **tetanospasmin**, more commonly referred to as tetanus toxin. Tetanus toxin (tetanospasmin) is the second most poisonous substance known, being surpassed in potency only by botulinum toxin; the human lethal dose of tetanus toxin is estimated to be 10^{-6} mg/kg.

Epidemiology.

Tetanus occurs worldwide and is endemic in 90 developing countries, but its incidence varies considerably. The most common form, neonatal (umbilical) tetanus, kills approximately 500,000 infants each year because the mother was not immunized; about 80% of these deaths occur in just 12 tropical Asian and African countries. In addition, an estimated 15,000–30,000 unimmunized women worldwide die each year of maternal tetanus that results from postpartum, postabortal, or postsurgical wound infection with *C. tetani*. Approximately 50 cases of tetanus are reported each year in the United States, mostly in persons older than 60 yr of age, but toddler-aged and neonatal cases also occur. One fifth of children in the United States 10–16 yr of age lack a protective antibody level. The majority of childhood cases of tetanus in the United States during the past decade have occurred in unimmunized children whose parents objected to vaccination.

Most non-neonatal cases of tetanus are associated with a traumatic injury, often a penetrating wound inflicted by a dirty object, such as a nail, splinter, fragment of glass, or unsterile injection, but a rare case may have no history of trauma. Tetanus occurring after illicit drug injection is becoming more common, whereas uncommon settings include animal bites, abscesses (including dental abscesses), ear and other body piercing, chronic skin ulceration, burns, compound fractures, frostbite, gangrene, intestinal surgery, ritual scarification, infected insect bites, and female circumcision. The disease also occurs after the use of contaminated suture material or after intramuscular injection of medicines, most notably quinine for chloroquine-resistant falciparum malaria.

Pathogenesis.

Tetanus occurs after introduced spores germinate, multiply, and produce tetanus toxin in the low oxidation-reduction potential (E_h) of an infected injury site. A plasmid carries the toxin gene; the toxin is released with vegetative bacterial cell death and subsequent lysis. Tetanus toxin (and the botulinum toxins) are 150-kd simple proteins consisting of a heavy (100 kd) and a light (50 kd) chain joined by a single disulfide bond. Tetanus toxin binds at the neuromuscular junction and enters the motor nerve by endocytosis, after which it undergoes retrograde axonal transport to the cytoplasm of the alpha-motoneuron. In the sciatic nerve, the transport rate was found to be 3.4?mm/hr. The toxin exits the motoneuron in the spinal cord and next enters adjacent spinal inhibitory interneurons, where it prevents release of the neurotransmitter a-aminobutyric acid (GABA). Tetanus toxin thus blocks the normal inhibition of antagonistic muscles, which is the basis of voluntary coordinated movement; in consequence, affected muscles sustain maximal contraction. The autonomic nervous system is also rendered unstable in tetanus.

The phenomenal potency of tetanus toxin is enzymatic in nature. The light chain of tetanus toxin (and of several of the botulinum toxins) is a zinc-containing endoprotease whose substrate is **synaptobrevin**, a constituent protein of the docking complex that enables the synaptic vesicle to fuse with the terminal cell membrane. The heavy chain of the toxin contains its binding and internalization domains.

C. tetani is not an invasive organism and its toxin-producing vegetative cells remain where introduced into the wound, which may or may not display local inflammatory changes and a mixed infectious flora.

Clinical Manifestations.

Tetanus may be either generalized, which is more common, or localized. The incubation period typically is 2–14 days, but it may be as long as months after the injury. In **generalized tetanus, trismus** (masseter muscle spasm, or **lockjaw**) is the presenting symptom in about half of cases. Headache, restlessness, and irritability are early symptoms, often followed by stiffness, difficulty chewing, dysphagia, and neck muscle spasm. The so-called **sardonic smile of tetanus (risus sardonicus)** results from intractable spasm of facial and buccal muscles. When the paralysis extends to abdominal, lumbar, hip, and thigh muscles, the patient may assume an arched posture of extreme hyperextension of the body, **opisthotonos,** with the head and the heels bent backward and the body bowed forward with only the back of the head and the heels touching the supporting surface. Opisthotonos is an equilibrium position that results from unrelenting total contraction of opposing muscles, all of

which display the typical **boardlike rigidity** of tetanus. Laryngeal and respiratory muscle spasm can lead to airway obstruction and asphyxiation. Because tetanus toxin does not affect sensory nerves or cortical function, the patient unfortunately remains conscious, in extreme pain, and in fearful anticipation of the next tetanic seizure. These seizures are characterized by sudden, severe tonic contractions of the muscles, with fist clenching, flexion, and adduction of the arms and hyperextension of the legs. Without treatment, the seizures range from a few seconds to a few minutes in length with intervening respite periods, but as the illness progresses, the spasms become sustained and exhausting. The smallest disturbance by sight, sound, or touch may trigger a tetanic spasm. Dysuria and urinary retention result from bladder sphincter spasm; forced defecation may occur. Fever, occasionally with a temperature as high as 40℃, is common because of the substantial metabolic energy consumed by spastic muscles. Notable autonomic effects include tachycardia, arrhythmias, labile hypertension, diaphoresis, and cutaneous vasoconstriction. The tetanic paralysis usually becomes more severe in the 1st wk after onset, stabilizes in the 2nd wk, and ameliorates gradually over the ensuing 1–4 wk.

Neonatal tetanus (tetanus neonatorum), the infantile form of generalized tetanus, typically manifests within 3–12 days of birth as progressive difficulty in feeding (i.e., sucking and swallowing), with associated hunger and crying. Paralysis or diminished movement, stiffness to the touch, and spasms, with or without opisthotonos, characterize the disease. The umbilical stump may hold remnants of dirt, dung, clotted blood, or serum, or it may appear relatively benign.

Localized tetanus results in painful spasms of the muscles adjacent to the wound site and may precede generalized tetanus. **Cephalic tetanus** is a rare form of localized tetanus involving the bulbar musculature that occurs with wounds or foreign bodies in the head, nostrils, or face. It also occurs in

association with chronic otitis media. Cephalic tetanus is characterized by retracted eyelids, deviated gaze, trismus, risus sardonicus, and spastic paralysis of tongue and pharyngeal musculature.

Diagnosis.

The picture of tetanus is one of the most dramatic in medicine, and the diagnosis may be established clinically. The typical setting is an unimmunized patient (and/or mother) who was injured or born within the preceding 2 wk and who presents with trismus, other rigid muscles, and a clear sensorium.

Routine laboratory studies are usually normal. A peripheral leukocytosis may result from a secondary bacterial infection of the wound or may be stress induced from the sustained tetanic spasms. The cerebrospinal fluid (CSF) is normal, although the intense muscle contractions may raise intracranial pressure. Neither the electroencephalogram nor the electromyogram shows a characteristic pattern. *C. tetani* is not always visible on Gram stain of wound material, and it is isolated in only about one third of cases.

DIFFERENTIAL DIAGNOSIS.

Fully developed, generalized tetanus cannot be mistaken for any other disease. However, trismus may result from parapharyngeal, retropharyngeal, or dental abscesses, or rarely, from acute encephalitis involving the brainstem. Either rabies or tetanus may follow an animal bite, and rabies may present as trismus with seizures. However, rabies may be distinguished from tetanus by its hydrophobia, marked dysphagia, predominantly clonic seizures, and CSF pleocytosis. Although strychnine poisoning may result in tonic muscle spasms and generalized seizure activity, it seldom produces trismus, and unlike tetanus, general relaxation usually occurs between spasms. Hypocalcemia may produce tetany, characterized by laryngeal and carpopedal spasms, but trismus is absent. Occasionally, epileptic seizures, narcotic withdrawal, or other drug reactions may suggest tetanus.

Treatment.

Management of tetanus requires eradication of *C. tetani* and the wound environment conducive to its anaerobic multiplication, neutralization of all accessible tetanus toxin, control of seizures and respiration, palliation and provision of meticulous supportive care, and, finally, prevention of recurrences.

Surgical wound excision and debridement is often needed to remove the foreign body or devitalized tissue that created anaerobic growth conditions. Surgery should be done promptly, after the administration of human tetanus immunoglobulin (TIG) and antibiotics. Excision of the umbilical stump in neonatal tetanus is no longer recommended.

Once tetanus toxin has begun its axonal ascent to the spinal cord, it cannot be neutralized by TIG. Accordingly, TIG is given as soon as possible to neutralize toxin that diffuses from the wound into the circulation before the toxin can bind at distant muscle groups. An optimal dose of TIG has not been determined. A single intramuscular injection of 500?U of TIG is sufficient to neutralize systemic tetanus toxin, but total doses as high as 3,000–6,000?U are also recommended. Infiltration of TIG into the wound is now considered unnecessary. If TIG is unavailable, use of human intravenous immunoglobulin (IVIG), which contains 4–90?U/mL of TIG, or of equine- or bovine-derived tetanus antitoxin (TAT), may be necessary. However, the optimal dosage of IVIG is not known, and it is not approved for this indication. The usual dose of TAT is 50,000–100,000?U, with half given intramuscularly and half intravenously, but as little as 10,000?U may be sufficient. TAT is not available in the United States. Approximately 15% of patients given the usual dose of TAT experience serum sickness. When using TAT, it is essential to check for possible sensitivity to horse serum and desensitization may be needed. The human-derived immunoglobulins are much preferred because of their longer half-life (30 days) and the virtual absence of allergic and serum sickness adverse effects. Intrathecal TIG, given to neutralize tetanus toxin in the spinal cord, is not effective.

Penicillin G (100,000?U/kg/24?hr divided q 4–6?hr IV for 10–14 days) remains the antibiotic of choice because of its effective clostridiocidal action and its diffusibility, an important consideration because blood flow to injured tissue may be

compromised. Metronidazole (500?mg q 8?hr IV for adults) appears to be equally effective. Erythromycin and tetracycline (for patients 8 yr old or older) are alternatives for penicillin-allergic patients.

All patients with generalized tetanus need muscle relaxants. Diazepam provides both relaxation and seizure control; the initial dose of 0.1–0.2/kg q 3–6?hr given intravenously is then titrated to control the tetanic spasms, after which it is sustained for 2–6 wk before its tapered withdrawal. Magnesium sulfate, other benzodiazepines (e.g., midazolam), chlorpromazine, dantrolene, and baclofen are also used. Intrathecal baclofen produces such complete muscle relaxation that apnea often ensues; like most other agents listed, baclofen should be used only in an intensive care unit setting. The best survival rates in generalized tetanus are achieved with neuromuscular blocking agents such as vecuronium and pancuronium, which produce a general flaccid paralysis that is then managed by mechanical ventilation. Autonomic instability is regulated with standard a- and ß- (or both) blocking agents; morphine has also proved useful.

Meticulous supportive care in a quiet, dark, secluded setting is most desirable. Because tetanic spasms may be triggered by minor stimuli, the patient should be sedated and protected from all unnecessary sounds, sights, and touch; and all therapeutic and other manipulations must be carefully scheduled and coordinated. Endotracheal intubation may not be required, but it should be done to prevent aspiration of secretions before laryngospasm develops. A tracheotomy kit should be immediately at hand for unintubated patients. However, endotracheal intubation and suctioning easily provoke reflex tetanic seizures and spasms, and early tracheostomy deserves consideration in severe cases not managed by pharmacologically induced flaccid paralysis. Cardiorespiratory monitoring, frequent suctioning, and maintenance of the substantial fluid, electrolyte, and caloric needs are fundamental. Careful nursing attention to mouth, skin, bladder, and bowel function is needed to avoid ulceration, infection, and obstipation. Prophylactic subcutaneous heparin use is sensible.

Complications.

The seizures and the severe, sustained rigid paralysis of tetanus predispose the patient to many complications. Aspiration of secretions and pneumonia may have begun before the first medical attention was received. Maintaining airway patency often mandates endotracheal intubation and mechanical ventilation with their attendant hazards, including pneumothorax and mediastinal emphysema. The seizures may result in lacerations of the mouth or tongue, in intramuscular hematomas or rhabdomyolysis with myoglobinuria and renal failure, or in long bone or spinal fractures. Venous thrombosis, pulmonary embolism, gastric ulceration with or without hemorrhage, paralytic ileus, and decubitus ulceration are constant hazards. Excessive use of muscle relaxants, an integral part of care, may produce iatrogenic apnea. Cardiac arrhythmias, including asystole, unstable blood pressure, and labile temperature regulation reflect disordered autonomic nervous system control that may be aggravated by inattention to maintenance of intravascular volume needs.

Prognosis.

Recovery in tetanus occurs through regeneration of synapses within the spinal cord and thereby the restoration of muscle relaxation. However, because an episode of tetanus does not result in the production of toxin-neutralizing antibodies, active immunization with tetanus toxoid at discharge with provision for completion of the primary series is mandatory.

The most important factor influencing outcome is the quality of supportive care. Mortality is highest in the very young and the very old. A favorable prognosis is associated with a long

incubation period, with the absence of fever, and with localized disease. An unfavorable prognosis is associated with a week or less between the injury and the onset of trismus and with 3 days or less between trismus and the onset of generalized tetanic spasms. Sequelae of hypoxic brain injury, especially in infants, include cerebral palsy, diminished mental abilities, and behavioral difficulties. Most fatalities occur within the 1st wk of illness. Reported case fatality rates for generalized tetanus range between 5% and 35% and for neonatal tetanus extend from <10% with intensive care treatment to >75% without it. Cephalic tetanus has an especially poor prognosis because of breathing and feeding difficulties.

Prevention.

Tetanus is an entirely preventable disease; a serum antibody titer of =0.01?U/mL is considered protective. Active immunization should begin in early infancy with combined diphtheria toxoid-tetanus toxoid-pertussis vaccine at 2, 4, and 6 mo of age, with a booster at 4–6 yr of age and at 10-yr intervals thereafter throughout adult life with tetanus-diphtheria (Td) toxoids. Immunization of women with tetanus toxoid prevents neonatal tetanus, and the World Health Organization is currently engaged in a global elimination of neonatal tetanus campaign through maternal immunization with at least two doses of tetanus toxoid. For unimmunized persons 7 yr of age or older, the primary immunization series consists of three doses of Td toxoid given intramuscularly, with the second given 4–6 wk after the first and the third given 6–12 mo after the second. However, unanticipated mass immunization campaigns in developing countries may rarely provoke a widespread hysterical reaction.

WOUND MANAGEMENT.

Tetanus prevention measures after trauma consist of inducing active immunity to tetanus toxin and of passively providing antitoxic antibody (Table 194–1). Tetanus prophylaxis is an essential part of all wound management, but specific measures depend on the nature of the injury and the immunization status of the patient. Tetanus toxoid should always be given after a dog or other animal bite, even though *C. tetani* is infrequently found in canine mouth flora. All nonminor wounds require human TIG except those in a fully immunized patient. In any other circumstances (e.g., patients with an unknown or incomplete immunization history; crush, puncture, or projectile wounds; wounds contaminated with saliva, soil, or feces; avulsion

injuries; compound fractures; or frostbite), 250?U of TIG should be given intramuscularly, and 500?U should be given for highly tetanus-prone wounds (i.e., unable to be debrided, with substantial bacterial contamination,

TABLE 194-1 -- **Tetanus Prophylaxis in Wound Management**

Three or more	No§	No	No	No

Adapted from Centers for Disease Control. Diphtheria, tetanus, and pertussis: Recommendations for vaccine use and other preventive measures. Recommendations of the Immunization Practices Advisory Committee (ACIP). MMWR 1991;40(RR-10):1–28.

**Such as, but not limited to wounds contaminated with dirt, feces, and saliva; puncture wounds; avulsions; wounds resulting from missiles, crushing, burns, and frostbite; and wounds extending into muscle.*
† For children <7 yr, DTaP or DTP is preferred to tetanus toxoid alone if < 3 doses of DTaP/DTP have been previously given; if pertussis vaccine is contraindicated, DT is given. For persons = 7 yr, Td is preferred to tetanus toxoid alone.
‡ TIG = tetanus immune globulin. TIG should be administered for tetanusprone wounds in HIV-1–infected patients regardless of the history of tetanus immunizations.
§Yes, if = 10 yr since the last dose.
Yes, if = 5 yr since the last dose. (More frequent boosters are not needed and can accentuate adverse events.)

or >24?hr old). If TIG is unavailable, then use of human IGIV may be considered. If neither of these products is available, then 3,000–5,000?U of equine- or bovine-derived TAT may be given intramuscularly after testing for hypersensitivity; even at this dose, serum sickness may occur.

The wound should have immediate, thorough surgical cleansing and debridement to remove foreign bodies and any necrotic tissue in which anaerobic conditions might develop. Tetanus toxoid should be given to stimulate active immunity and may be administered concurrently with TIG (or TAT) if given in separate syringes at widely separated sites. A tetanus toxoid booster (preferably Td) is given to all persons with *any* wound if their tetanus immunization status is unknown or incomplete. A booster is given to injured persons who have completed their primary immunization series if (1) the wound is clean and minor but =10 yr have passed since the last booster or (2) the wound is more serious and =5 yr have passed since the last booster. With delayed wound care, active immunization should be started at once. Although fluid tetanus toxoid produces a more rapid immune response than the adsorbed or precipitated toxoids, the adsorbed toxoid results in a more durable titer.

Chapter 195 - *Clostridium difficile*–Associated Diarrhea

Margaret C. Fisher

Clostridium difficile–associated diarrhea, also known as **pseudomembranous colitis** or **antibiotic-associated diarrhea**, is a major cause of nosocomial diarrhea. Uncommon causes of antibiotic-associated diarrhea include the enterotoxins of *Staphylococcus aureus* and *Clostridium perfringens*.

Etiology.

C. difficile is a ubiquitous spore-forming gram-positive anaerobic bacillus. The organism produces two toxins: **toxin A (enterotoxin)** acts on the intestinal mucosa to produce diarrhea; **toxin B (cytotoxin)** increases vascular permeability in low doses and is lethal to experimental animals in high doses. In general, strains produce either both toxins or neither toxin.

Epidemiology.

C. difficile-associated diarrhea usually occurs in patients receiving antimicrobial therapy. In children, some cases occur without prior antibiotics in the setting of altered bowel flora. Virtually all known antibiotics have been implicated; penicillins, broad-spectrum cephalosporins, and clindamycin are the most frequent offenders.

Newborns are often colonized with *C. difficile* during the first weeks of life, and colonization has been identified in approximately half of healthy infants during the first year of life. Many of these strains produce toxin. Carriage decreases to the adult rate of 1–3% by 2 yr of age. Illness is unusual in neonates and infants; the basis for this remains unknown. The incidence of toxin-mediated diarrhea peaks in children between the ages of 6 mo and 2 yr. *C. difficile*–associated diarrhea has been reported in children of all ages. Asymptomatic carriers are not at increased risk for disease unless given antibiotics.

Pathogenesis.

Normal gut flora appears to be protective. The administration of antibiotics that impair growth of normal flora but not *C. difficile* is the most common risk factor, but any process that disrupts the normal bowel flora (e.g., weaning, chemotherapy) or bowel motility (e.g., bowel stasis, bowel surgery) predisposes to *C. difficile*–associated diarrhea.

Toxin A binds to a specific receptor on the intestinal brush border; the binding site for toxin B is still undefined. Both toxins are internalized and act within cells to modify proteins, resulting in cell death. Inflammatory response contributes to the diarrhea and formation of **pseudomembranes**. Antibody to the toxins appears to prevent binding and modify or abort clinical disease.

Clinical Manifestations.

Clinical symptoms vary widely. Asymptomatic colonization is common in infants and young children. Illness is commonly a mild self-limited diarrhea without pseudomembranes, or it is explosive watery diarrhea with occult blood. The classic picture of pseudomembranous colitis is diarrhea with blood and mucus accompanied by fever, cramps, abdominal pain, nausea, and vomiting. Disease occurs during and as long as weeks after antibiotic therapy. Severe and extensive colitis occurs in children undergoing chemotherapy and has been reported in a few children with cystic fibrosis. *C. difficile* disease occasionally involves the small gut; in some hosts, bacteremia and abscess formation have been reported.

Diagnosis.

The diagnosis is confirmed by detecting *C. difficile* or its toxin in the stool of a patient with significant diarrhea or colitis in the setting of prior or current antimicrobial use.

It has been recommended in adult patients that the diagnosis of *C. difficile*–associated diarrhea be considered in any patient with diarrhea (=3 watery or unformed stools in 24?hr) or abdominal pain who has received antibiotics within 2 mo or whose diarrhea began >3 days after hospitalization.

Identification of toxin in a single stool specimen is the laboratory test usually used for diagnosis. Inoculation of stool filtrates into cell culture to detect cytotoxicity is considered the reference method; however, this is a labor-intensive method that requires 24–48?hr for results. Many clinical laboratories use enzyme immunoassay tests that detect toxin A only, or toxin A plus B. Testing for both toxins increases the yield of positive studies. Culture of the stool for *C. difficile* is time consuming and does not differentiate toxin-producing from non–toxin-producing strains. The interpretation of positive *C. difficile* culture or toxin in stool from children younger than 1 yr of age requires clinical correlation.

Findings at sigmoidoscopy or colonoscopy include pseudomembranous nodules and plaques characteristic of toxin-related colitis. Fecal leukocytes are present in

approximately one half of cases; occult or frank blood is common.

Treatment.

The first and essential step in treatment is the discontinuation of the current antibiotics, if possible. In most instances, this course combined with appropriate fluid and electrolyte replacement is sufficient. If symptoms persist, antibiotics cannot be discontinued, or the illness is severe, then oral metronidazole (20–40?mg/kg/24?hr divided q 6–8?hr PO) or vancomycin (25–40?mg/kg/24?hr divided q 6?hr PO) should be given for a 7–10 day course. Oral metronidazole is the preferred therapy for most children; it is less expensive, has an excellent response rate, and minimizes the emergence of vancomycin-resistant *Enterococcus*, which is especially important in hospitalized or institutionalized patients (Chapter 171).

Prognosis.

The initial response rate is >95%, but 5–30% of patients have clinical relapse, usually within 1–2 wk of treatment. These patients should be re-evaluated and treated again; most will respond to a second course of the original treatment. A few patients develop multiple recurrences, with short-lived responses to repeated treatment. Treatment strategies for these patients include oral cholestyramine, oral bacitracin, oral immunoglobulin, reconstitution of bowel flora with oral lactobacilli or baker's yeast, or instillation of fecal flora by tube feeding or enemas. None of these methods is effective for all cases.

Prevention.

C. difficile is often acquired nosocomially or in child-care settings. The spores of the organism are resistant to drying and to some disinfectants and frequently contaminate bathrooms and diaper changing areas of hospital rooms or child-care areas. Electronic thermometers are easily contaminated and have been implicated in several hospital outbreaks. Prevention of *C. difficile*–associated diarrhea requires meticulous hand hygiene, use of contact isolation, appropriate environmental cleaning, and appropriate use of antimicrobial agents.

Chapter 196 - Other Anaerobic Infections

Margaret C. Fisher

Anaerobic bacteria are the most numerous organisms colonizing humans. Anaerobes are present in soil and are normal inhabitants of all living animals, but infections caused by anaerobes are relatively uncommon. Anaerobes are relatively or entirely intolerant of exposure to oxygen. The ability to survive in the presence of oxygen varies greatly, with the majority of organisms being **facultative anaerobes**, that is, able to survive in the presence of oxygen but growing better when oxygen tension is reduced. Some anaerobes are **obligate anaerobes** and will not survive any exposure to oxygen.

Infections with anaerobes occur most commonly adjacent to mucosal surfaces and as mixed infections with aerobes. Optimal conditions for proliferation of anaerobes are circumstances with reduced oxygen tension. Traumatized areas, devascularized areas, and areas of crush injury are all ideal sites for anaerobic infections. Often both aerobic and anaerobic flora are inoculated

but local extension and bacteremia are most often due to the more virulent aerobes. Abscess formation evolves over days to weeks and generally involves a mixture of aerobes and anaerobes. Examples of such infections include appendicitis and abscesses: appendiceal, perirectal, peritonsillar, retropharyngeal, parapharyngeal, lung, and dental. Septic thrombophlebitis, a consequence of appendicitis, chronic sinusitis, pharyngitis, and otitis media, provides a route for spread of the infection to vital organs such as the liver, brain, or lungs.

Anaerobic infection is due to endogenous flora. Combinations of impaired physical barriers to infection, compromised tissue viability, alterations in endogenous flora, defects in host immunity, and anaerobic bacterial virulence factors contribute to infection with these normal inhabitants of mucous membranes. Virulence factors include capsules, toxins, enzymes, and fatty acids.

Clinical Manifestations.

Anaerobic infections occur in a variety of sites throughout the body (Table 196–1). Anaerobes exist synergistically with aerobes; infections with anaerobes are almost always polymicrobial and include aerobes.

CENTRAL NERVOUS SYSTEM.

Meningitis is rare, but it has occurred in neonates and as a complication of *Fusobacterium* infections of the ear and neck (Lemierre syndrome). Brain abscess and subdural empyema are usually polymicrobial, with anaerobes being commonly involved. Brain abscess occurs most commonly after spread of infection from sinuses, middle ear, or lung.

TABLE 196-1 -- **Infections Associated with Anaerobic Bacteria**

Site and Infection	Major Risk Factors	Anaerobic Bacteria[*]
Central Nervous System		
Cerebral abscess	Direct extension from contiguous sinusitis, otitis media, mastoiditis	(Polymicrobial)
Subdural empyema		*B. fragilis*[†]
Epidural abscess		*Fusobacterium*
		Peptostreptococcus
		Veillonella
Upper Respiratory Tract		
Dental abscess	Poor periodontal hygiene	*Peptostreptococcus*
Ludwig angina (cellulitis of sublingual-submandibular space)	Drugs that cause gum hypertrophy	*Fusobacterium*
Necrotizing gingivitis (Vincent stomatitis)		*P. melaninogenica*
Chronic otitis-mastoiditis-sinusitis		
Peritonsillar abscess		
Retropharyngeal abscess		
Lower Respiratory Tract		
Aspiration pneumonia	Periodontal disease	(Polymicrobial)
Necrotizing pneumonitis	Bronchial obstruction	*P. melaninogenica*
Lung abscess	Altered gag or consciousness	*B. intermedius*
Pulmonary empyema		*Fusobacterium*

		Peptostreptococcus, Eubacterium
		B. fragilis, Veillonella
Intra-abdominal		
Abscess	Appendicitis	(Polymicrobial)
Secondary peritonitis	Penetrating trauma (especially of the colon)	*B. fragilis*
		Other *Bacteroides*
		Clostridium
		Peptostreptococcus
		Eubacterium
		Fusobacterium
Female Genital Tract		
Bartholin abscess	Vaginosis	*B. fragilis*
Tubo-ovarian abscess	Intrauterine device	*B. bivius*
Endometritis		*Peptostreptococcus*
Pelvic cellulitis or thrombophlebitis		*Clostridium*
Salpingitis		*Mobiluncus*
Chorioamnionitis		Actinomycosis
Septic abortion		
Skin and Soft Tissue		
Cellulitis	Decubitus ulcers	(Varies with site and contamination with mouth or enteric flora)
Perirectal cellulitis	Abdominal wounds	
Myonecrosis (gas gangrene)	Pilonidal sinus	*Clostridium perfringens* (myonecrosis)
Necrotizing fasciitis	Trauma	*Bacteroides*
Synergistic gangrene	Human and animal bites	*Fusobacterium*
	Immunosuppressed or neutropenic patients	*Clostridium tertium*
		C. septicum
		Anaerobic streptococci
Bacteremia		
	Secondary to intra-abdominal infection, abscess, myonecrosis, or necrotizing fasciitis	*B. fragilis*
		Clostridium
		Anaerobic streptococci

**Infections may also be due to or involve aerobic bacteria as the sole or part of a mixed infection: brain abscess may contain microaerophilic streptococci; intra-abdominal infections may contain gram-negative enteric organisms and enterococci; and salpingitis may contain* Neisseria gonorrhoeae, *and* Chylamydia trachomatis.

† Bacteroides fragilis *is usually isolated from infections below the diaphragm except for brain abscesses.*

UPPER RESPIRATORY TRACT.

The respiratory tract is colonized by both aerobes and anaerobes. Anaerobic bacteria are involved in chronic sinusitis, chronic otitis media, peritonsillar infections, parapharyngeal and retropharyngeal abscesses, and periodontal infections. Anaerobic periodontal disease is most common in patients with poor dental hygiene and in those who are receiving drugs that result in hypertrophy of the gums. **Vincent angina,** or **trench mouth,** is an acute, fulminating, necrotizing infection of the gums and floor of the mouth. The disease is characterized by pain, foul breath, and pseudomembrane formation. Ludwig angina is a life-threatening cellulitis of the sublingual and submandibular spaces; disease spreads rapidly in the neck, and airway obstruction can occur.

Lemierre syndrome, or **postanginal sepsis**, is a suppurative infection of the lateral pharyngeal space with septic thrombophlebitis of the jugular vein leading to septic embolization to the lungs and/or central nervous system. Clinical signs include neck swelling and pain, trismus, dysphagia, and severe toxicity. *Fusobacterium necrophorum* is the most commonly involved organism; polymicrobial infection is frequent.

LOWER RESPIRATORY TRACT.

Anaerobic lung abscess, empyema, and anaerobic pneumonia are most common in children with swallowing dysfunction, in those with an increased incidence of aspiration, or an increased volume of aspiration and in the presence of a foreign body occluding the airway. All children and adults aspirate during sleep or during periods of unconsciousness. In most cases, the lung cilia and phagocytes clear particulate matter and microbes. If the aspiration is of high volume or high frequency or a foreign body blocks drainage, the ability of lung clearance mechanisms is overcome and infection ensues.

INTRA-ABDOMINAL INFECTION.

The digestive tract is colonized throughout by anaerobes. The density of organisms is highest in the colon, where anaerobes outnumber aerobes 1,000:1. Rupture of the gut leads to spillage of gut flora into the peritoneum, resulting in peritonitis that involves both aerobes and anaerobes. Bacteremia due to aerobes occurs early. As the infection is walled off in the peritoneum, an abscess composed of both aerobes and anaerobes is formed. Liver abscesses are rare in children; predisposing illnesses are appendicitis, inflammatory bowel disease, and biliary tract disease. In children with malignancies who are receiving chemotherapy, the gut mucosa is often damaged, leading to translocation of bacteria and focal invasion of bowel flora. Typhlitis, or necrotizing colitis, is a mixed infection of the gut wall usually beginning in the colon; abdominal pain, diarrhea, fever, and abdominal distention are common features. Empirical therapy of fever and neutropenia may not be optimal against the anaerobes involved in typhlitis.

GENITAL TRACT.

Genital tract infections in women often involve anaerobes. Pelvic inflammatory disease and tubo-ovarian abscesses are frequently due to mixed aerobes and anaerobes. Vaginitis can be caused by overgrowth of anaerobic flora. Anaerobes frequently contribute to chorioamnionitis and premature labor and may result in anaerobic bacteremia in the neonate. Although most of these bacteremias are transient, anaerobes occasionally cause invasive disease in the newborn.

SKIN AND SOFT TISSUE.

Anaerobic skin infections occur in the setting of bites, foreign bodies, and skin and tissue ulceration due to pressure necrosis or lack of adequate blood supply. Animal bites and human bites inoculate oral and skin flora into the subcutaneous tissues. Oral flora includes anaerobes, but the more virulent aerobic infections are responsible for most clinical infections (Chapter 707). The extent of the infection depends on the depth of the bite and the associated crush injury to the tissues.

Clostridial myonecrosis, or **gas gangrene**, is a rapidly progressive infection associated with *Clostridium perfringens*. **Necrotizing fasciitis** is a polymicrobial infection with acute onset and rapid progression, with significant morbidity and mortality. Group A streptococcus and *Staphylococcus aureus* occasionally are the sole pathogens. **Synergistic gangrene** is caused by synergistic infection between *S. aureus* or gram-negative bacilli and anaerobic streptococci. All of these are uncommon infections in healthy children. Early recognition with aggressive surgical debridement and antimicrobial therapy is necessary to limit morbidity and mortality.

OTHER SITES.

Occasionally the bone adjacent to anaerobic infection becomes infected by direct extension from contiguous infections or by direct inoculation associated with trauma. Anaerobic infections of the kidneys (renal and perirenal abscesses) and heart (pericarditis) are rare. **Enteritis necroticans (pigbel)** is a rare but often fatal gastrointestinal infection, which most commonly follows ingestion of a large meal in a previously starved child or adult. Recently hemorrhagic necrosis of the jejunum due to *C. perfringens* was reported in an American child with poorly controlled diabetes following ingestion of chitterlings (pork intestines).

Diagnosis.

The diagnosis of anaerobic infection requires a high index of suspicion and the collection of appropriate and adequate specimens for culture (Box 196–1). Cultures should be obtained in a manner that protects the specimen from contamination with mucosal bacteria and from exposure to ambient oxygen. Swab cultures of mucosal surfaces or of nasal secretions, respiratory specimens, and stool should not be sent for anaerobic culture because these sites normally harbor anaerobes. Aspirates of infected sites, abscess material, and biopsy specimens are ideal. The specimen should be protected from oxygen and transported to the laboratory immediately. A transport medium is used to increase the recovery of obligate anaerobes. Gram stains are useful; anaerobic infections are usually polymicrobial. Susceptibility testing of anaerobes is not always performed because it is labor intensive and time consuming. Several laboratory methods for susceptibility testing are available; a rapid and easy screening test is used to detect ß-lactamase production.

Box 196-1. Clues to Presumptive Diagnosis of Anaerobic Infections*

Infection that is contiguous to or in proximity with a mucosal surface colonized with anaerobic bacteria (oropharynx, intestinal-genitourinary tract)

Foul-smelling, putrid odor (present in 50% of anaerobic infections)

Severe tissue necrosis, abscesses, gangrene, or fasciitis

Gas formation in tissues (crepitus or on radiograph)

Failure to recover organisms using conventional aerobic microbiologic methods

Failure of organisms to grow after pretreatment with antibiotics effective against anaerobics

Failure of organisms to respond to antibiotics with poor efficacy against anaerobic bacteria (e.g., aminoglycosides)

against anaerobics

Failure of organisms to respond to antibiotics with poor efficacy against anaerobic bacteria (e.g., aminoglycosides)

Toxin-mediated syndromes (botulism, tetanus, gas gangrene, *Clostridium perfringens* food poisoning, *C. difficile* pseudomembranous colitis)

Typical infections associated with anaerobic bacteria (see Table 196–1)

Sterile pus

Septic thrombophlebitis

Septicemic syndrome with jaundice or intravascular hemolysis

Mixed polymorphic organisms on Gram stain

Typical Gram stain appearance:

- *Bacteroides species*—small, delicate, pleomorphic, pale, gram-negative bacilli
- *Fusobacterium nucleatum*—thin gram-negative bacilli with fusiform shape, pointed ends
- *F. necrophorum*—pleomorphism gram-negative bacilli with rounded ends
- *Peptostreptococcus*—gram-positive cocci similar to aerobic cocci
- *C. perfringens*—large, short, fat (boxcar-shaped) gram-positive bacilli

*Suspicion of anaerobic infection is critical before specimens are cultured to ensure optimal microbiologic techniques and prompt, appropriate therapy.

Treatment.

Treatment of anaerobic infections requires adequate drainage and appropriate antimicrobial therapy. Antibiotic therapy varies depending on the suspected or proven anaerobe involved. Some oral anaerobic flora are susceptible to penicillins, whereas many produce ß-lactamase. The drugs that are active against these organisms include metronidazole, penicillins combined with ß-lactamase inhibitors (ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam), carbapenems (imipenem and meropenem), clindamycin, cefoxitin, and chloramphenicol. Penicillin and vancomycin are active against the gram-positive anaerobes.

Aerobes are usually present with the anaerobes, necessitating broad-spectrum antibiotic combinations for empirical therapy. Specific therapy is based on culture results and clinical course.

For soft tissue infections, providing perfusion to the area is key to success; at times, a muscle flap or skin flap procedure is needed to ensure that nutrients and antimicrobial agents are brought to the affected area. Drainage of infected areas is often necessary for cure. Bacteria may survive in abscesses due to high bacterial inoculum, lack of bactericidal activity, and local conditions that facilitate bacterial proliferation. Aspiration is sometimes effective for small collections whereas incision and drainage may be required for larger abscesses. Extensive debridement and resection of all devitalized tissue is needed to control fasciitis and myonecrosis.

COMMON ANAEROBIC PATHOGENS

Clostridium.

Strains of *Clostridium* cause disease by infection, production of toxins, or both. More than 60 species have been identified, but only a few cause diseases in humans. The most commonly recovered organisms are *Clostridium difficile* (Chapter 195) and *C. perfringens*; other species encountered in human-disease include *C. botulinum* (Chapter 193), *C. tetani* (Chapter 194), *C. butyricum*, *C. septicum*, *C. sordellii*, *C. tertium*, and *C. histolyticus*.

C. perfringens produces a variety of toxins and virulence factors. Strains of *C. perfringens* are designated A through E. **Alpha toxin** is a phospholipase that hydrolyzes sphingomyelin and lecithin and is produced by all strains. This toxin causes hemolysis, platelet lysis, increased capillary permeability, and hepatotoxicity. **Beta toxin**, produced by strains B and C, causes hemorrhagic necrosis of the small bowel. **Epsilon toxin**, produced by B and D strains, injures vascular endothelial cells leading to increased vascular permeability, edema, and organ dysfunction. **Iota toxin**, produced by E strains, causes dermal edema. An enterotoxin is produced by type A and some type C and D strains. Hemolysins and a variety of enzymes are produced by many *C. perfringens* strains.

MYONECROSIS.

C. perfringens is the major cause of myonecrosis, or gas gangrene, a rapidly progressive infection of soft tissue. In compromised hosts, especially patients

receiving cancer chemotherapy, *C. septicum* is a cause of rapidly fatal gas gangrene. A clue to the diagnosis is pain out of proportion to the clinical appearance of the wound. Infection progresses rapidly with edema, swelling, myonecrosis, and sometimes crepitation of the soft tissue. Hypotension, mental confusion, shock, and renal failure are common. A characteristic sweet odor is present in the serosanguineous discharge. Gram stain of the exudate reveals gram-positive rods and a few leukocytes. Early and complete debridement with excision of necrotic tissue is key to controlling the infection. High-dose penicillin (250,000?U/kg/24?hr divided q 4–6?hr IV) or clindamycin (25–40?mg/kg/24?hr divided q 6–8?hr IV) should be started immediately. The role of hyperbaric oxygen remains unclear but has been beneficial in several studies. The prognosis is poor even with early, aggressive therapy.

FOOD POISONING.

C. perfringens type A produces an enterotoxin that causes food poisoning (Chapter 705). The intoxication results in the acute onset of watery diarrhea and crampy abdominal pain. The usual foods containing toxin are improperly prepared meats and gravies. A specific diagnosis is rarely made in children with food poisoning. Therapy consists of rehydration and electrolyte replacement if necessary. The illness resolves spontaneously within 24?hr of onset. Prevention requires the maintenance of hot food at a temperature of =74°C.

GASTROENTERITIS.

A severe gastroenteritis, termed **enteritis necroticans** or **pigbel**, is caused by type C strains of *C. perfringens* that produce beta toxin. The disease occurs most commonly in Papua New Guinea, and is related to particular dietary habits and malnutrition. Recently, enteritis necroticans was recognized in the United States in a 12-yr-old boy with poorly controlled diabetes mellitus; the source of the infection was undercooked pork chitterlings.

Bacteroides and Prevotella.

Bacteroides fragilis is one of the more virulent of the anaerobes. It is the anaerobic pathogen that is most frequently recovered from blood cultures and cultures of tissue or pus. The most common infection in children is infection associated with appendicitis. The organism is part of normal colonic flora but is not common in the mouth or respiratory tract. *B. fragilis* is usually found as part of a polymicrobial appendiceal and other intra-abdominal abscesses and is involved in genital tract infections such as pelvic inflammatory disease and tubo-ovarian abscess. *Prevotella* are normal oral flora; infection involves gums, teeth, tonsils, and parapharyngeal spaces. Both organisms are sometimes involved in anaerobic pneumonia and lung abscess.

Strains of *B. fragilis* and *P. melaninogenica* produce ß-lactamase and thus are resistant to penicillins. Antibiotics of choice include ticarcillin-clavulanate, piperacillin/tazobactam, cefoxitin, metronidazole, clindamycin, imipenem, meropenem, and chloramphenicol. Chloramphenicol is rarely used because of toxicity and failure of therapy for intra-abdominal infection. Because infections involving these organisms are polymicrobial, therapy should include antimicrobial agents active against the probable aerobic pathogens. Drainage of abscesses and debridement of necrotic tissue are often required for control of these infections.

Fusobacterium.

Fusobacterium inhabit the intestine, respiratory, and female genital tracts. These organisms are more virulent than most of the normal anaerobic flora and have been reported to cause bacteremia and a variety of rapidly progressive infections. Lemierre syndrome, bone and joint infection, and abdominal and genital tract infections are most common. Some strains produce ß-lactamase and are thus resistant to penicillins.

Veillonella.

Veillonella are normal flora of the mouth, upper respiratory tract, intestine, and vagina. These anaerobes rarely cause infection; strains are recovered as part of the polymicrobial flora causing abscess, chronic sinusitis, empyema, peritonitis, and wound infection. *Veillonella* are susceptible to penicillins, cephalosporins, clindamycin, metronidazole, and carbapenems.

Anaerobic Cocci.

Peptostreptococcus are normal flora of the skin, respiratory tract, and gut. These organisms are often present in brain abscesses, chronic sinusitis, chronic otitis, and lung abscesses. Such infections are often polymicrobial, and therapy is aimed at the accompanying aerobes as well as the anaerobes. Most of the gram-positive cocci are susceptible to penicillin, cephalosporins, carbapenems, and vancomycin.

Section 5 - *Mycobacterial Infections*

Chapter 197 - Tuberculosis (*Mycobacterium tuberculosis*)

Flor M. Munoz
Jeffrey R. Starke

During the last decade of the 20th century the number of new cases of tuberculosis increased worldwide. Currently, 95% of tuberculosis cases occur in developing countries, where HIV/AIDS epidemics have had the greatest impact, and where resources are often unavailable for proper identification and treatment of these diseases. In many industrialized countries, most cases of tuberculosis occur in foreign-born populations. The World Health Organization (WHO) estimates that more than 8 million new cases of tuberculosis occur and approximately 3 million people die of the disease worldwide each year. Almost 1.3 million cases and 450,000 deaths occur in children each year. More than one third of the world's population is infected with *Mycobacterium tuberculosis*. If present trends continue, 10.5 million new cases are expected to occur annually by 2005, with Africa having more cases than any other region of the world. In the United States, after a resurgence in the late 1980s, the total number of cases of tuberculosis began to decrease in 1992, but tuberculosis continues to be a public health concern.

Etiology.

There are five closely related mycobacteria in the *Mycobacterium tuberculosis* complex: *M. tuberculosis*, *M. bovis*, *M. africanum*, *M. microti*, and *M. canetti*. All belong to the order Actinomycetales and the family Mycobacteriaceae. *M. tuberculosis* is the most important cause of tuberculosis disease in humans. The tubercle bacilli are non–spore-forming, nonmotile, pleomorphic, weakly Gram-positive curved rods 2–4?µm long. They may appear beaded or clumped in stained clinical specimens or culture media. They are obligate aerobes that grow in synthetic media containing glycerol as the carbon source and ammonium salts as the

nitrogen source (e.g., Loewenstein Jensen culture media). These mycobacteria grow best at 37–41°C, produce niacin, and lack pigmentation. A lipid-rich cell wall accounts for resistance to the bactericidal actions of antibody and complement. A hallmark of all mycobacteria is acid-fastness—the capacity to form stable mycolate complexes with arylmethane dyes such as crystal violet, carbolfuchsin, auramine, and rhodamine. Once stained, they resist decoloration with ethanol and hydrochloric or other acids.

Mycobacteria grow slowly, their generation time being 12–24?hr. Isolation from clinical specimens on solid synthetic media usually takes 3–6 wk, and drug-susceptibility testing requires an additional 4 wk. However, growth can be detected in 1–3 wk in selective liquid medium using radiolabeled nutrients (the BACTEC radiometric system), and drug susceptibilities can be determined in an additional 3–5 days. The presence of *M. tuberculosis* in clinical specimens can be detected within hours using nucleic acid amplification (NAA) tests, including polymerase chain reaction, that employ a DNA probe complementary to mycobacterial DNA or RNA. Data from children are limited, but the sensitivity of some NAA techniques is similar to that for culture for pulmonary tuberculosis and is generally better than culture for extrapulmonary disease. Restriction fragment length polymorphism (RFLP) profiling of mycobacteria has become a helpful tool to study the epidemiology of tuberculosis.

Epidemiology.

Latent tuberculosis infection (LTBI) occurs after the inhalation of infective droplet nuclei containing *M. tuberculosis*. A reactive tuberculin skin test and the absence of clinical and radiographic manifestations are the hallmark of this stage. Tuberculosis disease occurs when signs and symptoms or radiographic changes become apparent. The word *tuberculosis* refers to disease. Untreated infants with LTBI have up to a 40% likelihood of developing tuberculosis, with the risk of progression decreasing gradually through childhood to adult lifetime rates of 5–10%. The greatest risk for progression occurs in the first 2 yr after infection.

The WHO estimates that one third of the world's population—2 billion people—are infected with *M. tuberculosis*. Infection rates are highest in Africa, Asia, and Latin America (Fig. 197–1). The global burden of tuberculosis continues to grow due to several factors, which include the impact of HIV epidemics, population migration patterns, increasing poverty, social upheaval and crowded living conditions in developing countries and in inner city populations in developed countries, inadequate health coverage and poor access to health services, and inefficient tuberculosis control programs.

Tuberculosis case rates decreased steadily in the United States during the first half of the 20th century, long before the advent of antituberculosis drugs, as a result of improved living conditions. A resurgence of tuberculosis in the late 1980s was associated primarily with the HIV epidemic and multidrug resistance adding to increased immigration and poor tuberculosis control (Fig. 197–2). Since 1992, the number of reported cases of tuberculosis has decreased each year, reaching a record low of 15,989 cases (rate of 5.6/100,000 population) in the year 2001. Of these, only 931 (6%) cases occurred in children <15 yr of age (rate 1.5/100,000 population). The decline in overall incidence was mostly due to a substantial decrease in cases in individuals born in the United States. Forty-nine percent of all cases were among foreign-born persons, a rate of 26.6/100,000 population. The total number of cases among foreign-born individuals increased

---

Figure 197-1 Estimated incidence of tuberculosis in the world, 2001. (Redrawn from World Health Organization Global Report on Tuberculosis, 2002. The designations employed and the presentation of material on this map do not imply any opinion on the part of the World Health Organization concerning the legal status of any country, city, or area or of its authorities, or concerning the delineation of its frontiers or boundaries.)

Figure 197-2 Observed rates of childhood tuberculosis in the United States, 1981–2001. The total number of tuberculosis cases peaked in 1992, decreasing by 5%–7% annually since. (From Centers for Disease Control and Prevention, 2002.)

4% between 1992 and 2000. In all age groups, the proportion of reported cases was strikingly higher in foreign-born and nonwhite individuals, even though the number of cases among foreign-born children <15 yr has declined. In white populations in the United States, tuberculosis rates are highest among the elderly who acquired the infection decades ago. In contrast, among nonwhite populations, tuberculosis is most common in young adults and children <5 yr of age. The age range of 5–14 yr is often called the “favored age” because in all human populations this group has the lowest rate of tuberculosis disease. Among adults, two thirds of cases occur in males, but there is no significant difference in gender distribution in childhood.

In the United States, most children are infected with *M. tuberculosis* in their home by someone close to them but outbreaks of childhood tuberculosis also occur in elementary and high schools, nursery schools, daycare centers, homes, churches, school buses, and sports teams. HIV-infected adults with tuberculosis can transmit *M. tuberculosis* to children, and children with HIV infection are at increased risk of developing tuberculosis after infection. Population groups at high risk for acquiring tuberculosis infection and factors that increase the risk to progress from LTBI to tuberculosis are described in Box 197–1 .

The incidence of drug-resistant tuberculosis has increased dramatically throughout the world. In the United States, about

Box 197-1. Groups at High Risk for Acquiring Tuberculosis Infection and Developing Disease in Developed Countries

RISK FOR TUBERCULOSIS INFECTION

- Children exposed to high-risk adults
- Foreign-born persons from high-prevalence countries
- Poor and indigent persons, especially in large cities
- Homeless persons
- Persons who inject drugs
- Present and former residents or employees of correctional institutions, homeless shelters, and nursing homes
- Health care workers caring for high-risk patients

RISK FOR PROGRESSION TO TUBERCULOSIS DISEASE ONCE INFECTED

- Infants and children =4 yr of age, especially those <2 yr of age
- Adolescents and young adults
- Persons co-infected with HIV
- Persons with skin test conversion in the past 1–2 yr
- Persons who are immunocompromised, especially in cases of malignancy and solid organ transplantation, immunosuppressive medical treatments, diabetes mellitus, chronic renal failure, silicosis, and malnutrition

immunocompromised, especially in cases of malignancy and solid organ transplantation, immunosuppressive medical treatments, diabetes mellitus, chronic renal failure, silicosis, and malnutrition

8% of *M. tuberculosis* isolates are resistant to at least isoniazid, whereas 1% are resistant to both isoniazid and rifampin. Resistance to isoniazid remained relatively stable between 1992 and 2000, but the proportion of cases that were multidrug resistant decreased from 1.7% to 1%. In some countries drug resistance rates range from 20–50%. The major reasons for the development of drug resistance are poor patient adherence to treatment and provision of inadequate drug regimens by the physician or national tuberculosis program

TRANSMISSION.

Transmission of *M. tuberculosis* is person to person, usually by airborne mucus droplet nuclei, particles 1–5?µm in diameter that contain *M. tuberculosis*. Transmission rarely occurs by direct contact with an infected discharge or a contaminated fomite. The chance of transmission increases when the patient has an acid-fast smear of sputum, an extensive upper lobe infiltrate or cavity, copious production of thin sputum, and severe and forceful cough. Environmental factors, especially poor air circulation, enhance transmission. Most adults no longer transmit the organism within several days to 2 wk after beginning adequate chemotherapy, but some patients remain infectious for many weeks. Young children with tuberculosis rarely infect other children or adults. Tubercle bacilli are sparse in the endobronchial secretions of children with pulmonary tuberculosis, and cough is often absent or lacks the tussive force required to suspend infectious particles of the correct size. However, children and adolescents with adult-type pulmonary tuberculosis can transmit the organism. Airborne transmission of *M. bovis* and *M. africanum* can also occur. *M. bovis* may penetrate the gastrointestinal mucosa or invade the lymphatic tissue of the oropharynx when large numbers of the organism are ingested. Human infection with *M. bovis* is rare in developed countries as a result of the pasteurization of milk and effective tuberculosis control programs for cattle.

Pathogenesis.

The primary complex of tuberculosis includes local infection at the portal of entry and the regional lymph nodes that drain the area. The lung is the portal of entry in over 98% of cases. The tubercle bacilli multiply initially within alveoli and alveolar ducts. Most of the bacilli are killed, but some survive within nonactivated macrophages, which carry them through lymphatic vessels to the regional lymph nodes. When the primary infection is in the lung, the hilar lymph nodes usually are involved, although an upper lobe focus may drain into paratracheal nodes. The tissue reaction in the lung parenchyma and lymph nodes intensifies over the next 2–12 wk as the organisms grow in number and tissue hypersensitivity develops. The parenchymal portion of the primary complex often heals completely by fibrosis or calcification after undergoing caseous necrosis and encapsulation. Occasionally, this portion continues to enlarge, resulting in focal pneumonitis and pleuritis. If caseation is intense, the center of the lesion liquefies and empties into the associated bronchus, leaving a residual cavity.

The foci of infection in the regional lymph nodes develop some fibrosis and encapsulation, but healing is usually less complete than in the parenchymal lesion.

Viable *M. tuberculosis* can persist for decades within these foci. In most cases of initial tuberculosis infection the lymph nodes remain normal in size. However, hilar and paratracheal lymph nodes that enlarge significantly as part of the host inflammatory reaction may encroach on a regional bronchus. Partial obstruction of the bronchus caused by external compression may cause hyperinflation in the distal lung segment. Complete obstruction results in atelectasis. Inflamed caseous nodes can attach to the bronchial wall and erode through it, causing endobronchial tuberculosis or a fistula tract. The caseum causes complete obstruction of the bronchus. The resulting lesion, a combination of pneumonitis and atelectasis, has been called a collapse-consolidation or segmental lesion (Fig. 197–3).

During the development of the primary complex, tubercle bacilli are carried to most tissues of the body through the blood

Figure 197-3 Right-sided hilar lymphadenopathy and collapse-consolidation lesions of primary tuberculosis in a 4-yr-old child.

and lymphatic vessels. Although seeding of the organs of the reticuloendothelial system is common, bacterial replication is more likely to occur in organs with conditions that favor their growth, such as the lung apices, brain, kidneys, and bones. Disseminated tuberculosis occurs if the number of circulating bacilli is large and the host cellular immune response is inadequate. More often the number of bacilli is small, leading to clinically inapparent metastatic foci in many organs. These remote foci usually become encapsulated, but they may be the origin of both extrapulmonary tuberculosis and reactivation tuberculosis in some individuals.

The time between initial infection and clinically apparent disease is variable. Disseminated and meningeal tuberculosis are early manifestations, often occurring within 2–6 mo of the infection. Clinically significant lymph node or endobronchial tuberculosis usually appears within 3–9 mo. Lesions of the bones and joints take several years to develop, whereas renal lesions may become evident decades after infection. From 25–35% of children with tuberculosis develop extrapulmonary manifestations compared with about 10% of immunocompetent adults.

Pulmonary tuberculosis that occurs more than a year after the primary infection is usually caused by endogenous regrowth of bacilli persisting in partially encapsulated lesions. This reactivation tuberculosis is rare in children but is common among adolescents and young adults. The most common form is an infiltrate or cavity in the apex of the upper lobes, where oxygen tension and blood flow are great.

The risk of dissemination of *M. tuberculosis* is very high in HIV-infected persons. Reinfection also can occur in persons with advanced HIV or AIDS. In immunocompetent individuals the response to the initial infection with *M. tuberculosis* usually provides protection against reinfection when a new exposure occurs. However exogenous reinfection has been reported to occur in adults without immune compromise in highly endemic areas.

PREGNANCY AND THE NEWBORN.

Pulmonary and particularly extrapulmonary tuberculosis other than lymphadenitis in a pregnant woman is associated with increased risk for prematurity, fetal growth retardation, low birthweight and perinatal mortality. Congenital tuberculosis is rare because the most common result of female genital tract tuberculosis is infertility. Congenital transmission usually occurs from a lesion in the placenta through the umbilical vein. Primary infection in the mother just before or during pregnancy is more likely to cause congenital infection than is reactivation of a previous infection. The tubercle bacilli first reach the fetal liver, where a primary focus with periportal lymph node involvement may occur. Organisms pass through the liver into the main fetal circulation and infect many organs. The bacilli in the lung usually remain dormant until after birth, when oxygenation and pulmonary circulation increase significantly. Congenital tuberculosis may also be caused by aspiration or ingestion of infected amniotic fluid. However, the most common route of infection for the neonate is postnatal airborne transmission from an adult with infectious pulmonary tuberculosis.

IMMUNITY.

Conditions that adversely affect cell-mediated immunity predispose to progression from tuberculosis infection to disease. Rare specific genetic defects associated with deficient cell mediated immunity in response to mycobacteria include interleukin-12 receptor B1 (IL-12B1) deficiency and complete and partial interferon-? receptor 1 chain deficiencies. Tuberculosis infection is associated with a humoral antibody response, which appears to play little role in host defense. Shortly after infection, tubercle bacilli replicate in both free alveolar spaces and within inactivated alveolar macrophages. Sulfatides in the mycobacterial cell wall inhibit fusion of the macrophage phagosome and lysosomes, allowing the organisms to escape destruction by intracellular enzymes. Cell-mediated immunity develops 2–12 wk after infection, along with tissue hypersensitivity. After bacilli enter macrophages, lymphocytes that recognize mycobacterial antigens proliferate and secrete lymphokines and other mediators that attract other lymphocytes and macrophages to the area. Certain lymphokines activate macrophages, causing them to develop high concentrations of lytic enzymes that enhance their mycobactericidal capacity. A discrete subset of regulator helper and suppressor lymphocytes modulates the immune response. Development of specific cellular immunity prevents progression of the initial infection in most individuals.

The pathologic events in the initial tuberculosis infection seem to depend on the balance among the mycobacterial antigen load; cell-mediated immunity, which enhances intracellular killing; and tissue hypersensitivity, which promotes extracellular killing. When the antigen load is small and the degree of tissue sensitivity is high, granuloma formation results from the organization of lymphocytes, macrophages, and fibroblasts. When both antigen load and the degree of sensitivity are high, granuloma formation is less organized. Tissue necrosis is incomplete, resulting in formation of caseous material. When the degree of tissue sensitivity is low, as is often the case in infants or immunocompromised individuals, the reaction is diffuse and the infection is not well contained, leading to dissemination and local tissue destruction. Tissue necrosis factor and other cytokines released by specific lymphocytes promote cellular destruction and tissue damage in susceptible

individuals.

TUBERCULIN SKIN TESTING.

The development of delayed-type hypersensitivity (DTH) in most individuals infected with the tubercle bacillus makes the tuberculin skin test a useful diagnostic tool. Multipuncture tests (MPTs) are not as accurate as the Mantoux test because the exact dose of tuberculin antigen introduced into the skin cannot be controlled. The MPTs should no longer be used in pediatric practice.

The **Mantoux tuberculin skin test** is the intradermal injection of 0.1?mL containing 5 tuberculin units (TU) of purified protein derivative (PPD) stabilized with Tween 80. T cells sensitized by prior infection are recruited to the skin where they release lymphokines that induce induration through local vasodilatation, edema, fibrin deposition, and recruitment of

other inflammatory cells to the area. The amount of induration in response to the test should be measured by a trained person 48–72?hr after administration. Occasional patients will have the onset of induration >72?hr after placement; this is a positive result. Immediate hypersensitivity reactions to tuberculin or other constituents of the preparation are short lived (<24?hr) and not considered a positive result. Tuberculin sensitivity develops 3 wk to 3 mo—most often in 4–8 wk—after inhalation of organisms. Host-related factors, including very young age, malnutrition, immunosuppression by disease or drugs, viral infections (e.g., measles, mumps, varicella, influenza), vaccination with live-virus vaccines, and overwhelming tuberculosis can depress the skin test reaction in a child infected with *M. tuberculosis*. Corticosteroid therapy may decrease the reaction to tuberculin, but the effect is variable. Tuberculin skin testing done at the time of initiating corticosteroid therapy is usually reliable. Approximately 10% of immunocompetent children with tuberculosis disease—up to 50% of those with meningitis or disseminated disease—do not react initially to PPD; most become reactive after several months of antituberculosis therapy. Nonreactivity may be specific to tuberculin or more global to a variety of antigens, so positive “control” skin tests with a negative tuberculin test never rule out tuberculosis. The most common reasons for a false-negative skin test are poor technique or misreading of the results.

False-positive reactions to tuberculin can be caused by cross sensitization to antigens of nontuberculous mycobacteria (NTM), which generally are more prevalent in the environment as one approaches the equator. These cross reactions are usually transient over months to years and produce less than 10–12?mm of induration. Previous vaccination with bacille Calmette-Guérin (BCG) also can cause a reaction to a tuberculin skin test. Approximately one half of infants who receive a BCG vaccine never develop a reactive tuberculin skin test, and the reactivity usually wanes in 2–3 yr in those with initially positive skin tests. Older children and adults who receive a BCG vaccine are more likely to develop tuberculin reactivity, but most lose the reactivity by 5–10 yr after vaccination. When skin test reactivity is present, it usually causes <10?mm of induration, although larger reactions occur in some individuals. In general, a tuberculin skin reaction =10?mm in a BCG-vaccinated child or adult indicates infection with *M. tuberculosis*, which necessitates further diagnostic evaluation and treatment. Prior vaccination with BCG is never a contraindication to tuberculin testing.

The appropriate size of induration indicating a positive Mantoux tuberculin skin test varies with related epidemiologic and risk factors. In children with no risk factors for tuberculosis skin test reactions are usually false-positive results. For this reason, the American Academy of Pediatrics (AAP) and Centers for Disease Control and Prevention (CDC) discourage routine testing of children, and recommend targeted tuberculin testing of children at risk identified through periodic screening surveys conducted by the primary care provider. Possible exposure to an adult with or at high risk for infectious pulmonary tuberculosis is the most crucial risk factor for children. Reaction size limits for determining a positive tuberculin test result vary with the individual's risk of infection (Box 197–2). For adults and children at the highest risk of having infection progress to disease—those with recent contact with infectious persons, clinical illnesses consistent with tuberculosis, or HIV infection or other immunosuppression—a reactive area =5?mm is classified as a positive result, indicating infection with *M. tuberculosis*. For other high-risk groups, a reactive area =10?mm is considered positive. For low-risk persons, especially those residing in communities where the prevalence of tuberculosis is low, the cutoff point for a positive reaction is =15?mm. An increase of induration of =10?mm within a 2-yr period is considered a tuberculin skin test conversion at any age. Classifying children with this scheme depends on the willingness and ability of the clinician and family to develop

Box 197-2. Definition of a Positive Tuberculin Skin Test Reaction Result in Infants, Children, and Adolescents

INDURATION =5?mm

Close contacts of known or suspected case of tuberculosis disease

Children having clinical or radiographic findings of tuberculosis disease

Children with immunosuppressive conditions, including HIV and organ transplantation

Patients receiving immunosuppressive therapy, including immunosuppressive doses of corticosteroids (=15?mg/24?hr prednisone or equivalent for =1 mo)

immunosuppressive therapy, including immunosuppressive doses of corticosteroids (=15?mg/24?hr prednisone or equivalent for =1 mo)

INDURATION =10?mm

- Infants and children =4 yr of age
- Children with underlying medical conditions or behaviors that increase risk (renal disease, hematologic disorders, diabetes mellitus, malnutrition, injection drug use)
- Children with frequent exposure to adults at high risk
- Birth or recent immigration (<5 yr) from a high-prevalence country
- Children with travel to or exposure to visitors from high-prevalence countries

INDURATION =15?mm

- Children >4 yr of age and older without any risk factors

a thorough exposure history for the child and the adults who care for the child. To interpret the tuberculin skin test correctly, the clinician must clearly understand the epidemiology of tuberculosis in the community and the correct indication for tuberculin testing of the individual.

Clinical Manifestations and Diagnosis.

The majority of children with tuberculosis infection develop no signs or symptoms at any time. Occasionally, infection is marked by low-grade fever and mild cough, and rarely by high fever, cough, malaise, and flu-like symptoms that resolve within a week. The proportion of extrapulmonary tuberculosis cases has increased over the past 2 decades in the United States. About 15% of adult tuberculosis cases are extrapulmonary, and 25–30% of children with tuberculosis have an extrapulmonary presentation.

PRIMARY PULMONARY DISEASE.

The primary pulmonary complex includes the parenchymal focus and the regional lymph nodes. About 70% of lung foci are subpleural, and localized pleurisy is common. The initial parenchymal inflammation usually is not visible on chest radiograph, but a localized, nonspecific infiltrate may be seen before the development of tissue hypersensitivity. All lobar segments of the lung are at equal risk of initial infection. Two or more primary foci are present in 25% of cases. The hallmark of primary tuberculosis in the lung is the relatively large size of the regional lymphadenitis compared with the relatively small size of the initial lung focus. As DTH develops, the hilar lymph nodes continue to enlarge in some children, especially infants, compressing the regional bronchus and causing obstruction. The usual sequence is hilar lymphadenopathy, focal hyperinflation, and then atelectasis. The resulting radiographic shadows have been called collapse-consolidation or segmental tuberculosis (see Fig. 197–3). Rarely, inflamed caseous nodes attach to the endobronchial wall and erode through it, causing endobronchial tuberculosis or a fistula tract. The caseum causes complete obstruction of the bronchus, resulting in extensive infiltrate and collapse. Enlargement of the subcarinal lymph nodes can cause compression of the esophagus and, rarely, a bronchoesophageal fistula.

Most cases of tuberculous bronchial obstruction in children resolve fully with appropriate treatment. Occasionally, there is residual calcification of the primary focus or regional lymph nodes. The appearance of calcification implies that the lesion has been present for at least 6–12 mo. Healing of the segment can be complicated by scarring or contraction associated with cylindrical bronchiectasis, but this is rare.

Children may have lobar pneumonia without impressive hilar lymphadenopathy. If the primary infection is progressively destructive, liquefaction of the lung parenchyma can lead to formation of a thin-walled primary tuberculosis cavity. Rarely, bullous tuberculous lesions can occur in the lungs and lead to pneumothorax if they rupture. Erosion of a parenchymal focus of tuberculosis into a blood or lymphatic vessel may result in dissemination of the bacilli and a **miliary pattern**, with small nodules evenly distributed on the chest radiograph.

The symptoms and physical signs of primary pulmonary tuberculosis in children are surprisingly meager considering the degree of radiographic changes often seen. More than 50% of infants and children with radiographically moderate to severe pulmonary tuberculosis have no physical findings and are discovered only by contact tracing. Infants are more likely to experience signs and symptoms. Nonproductive cough and mild dyspnea are the most common symptoms. Systemic complaints such as fever, night sweats, anorexia, and decreased activity occur less often. Some infants have difficulty gaining weight or develop a true failure-to-thrive syndrome that often does not improve significantly until several months of effective treatment have been taken. Pulmonary signs are even less common. Some infants and young children with bronchial obstruction have localized wheezing or decreased breath sounds that may be accompanied by tachypnea or, rarely, respiratory distress. These pulmonary symptoms and signs are occasionally alleviated by antibiotics, suggesting bacterial superinfection.

The most specific confirmation of pulmonary tuberculosis is isolation of *M. tuberculosis*. Sputum specimens for culture should be collected from adolescents and older children who are capable to expectorate. The best culture specimen in young children is the early morning gastric acid obtained before the child has arisen

and peristalsis has emptied the stomach of the pooled secretions that have been swallowed overnight. Even under optimal conditions, though, three consecutive morning gastric aspirates yield the organisms in <50% of cases. The culture yield from bronchoscopy is even lower, but this procedure may demonstrate the presence of endobronchial disease or a fistula. Negative cultures never exclude the diagnosis of tuberculosis in a child. For most children, the presence of a positive tuberculin skin test, an abnormal chest radiograph consistent with tuberculosis, and history of exposure to an adult with infectious tuberculosis is adequate proof that the disease is present. The drug susceptibility test results from the adult source case's isolate can be used to determine the best therapeutic regimen for the child. Cultures should be obtained from the child whenever the source case is unknown or the source case has possible drug-resistant tuberculosis.

PROGRESSIVE PRIMARY PULMONARY DISEASE.

A rare but serious complication of tuberculosis in a child occurs when the primary focus enlarges steadily and develops a large caseous center. Liquefaction may cause formation of a primary cavity associated with large numbers of tubercle bacilli. The enlarging focus may slough necrotic debris into the adjacent bronchus, leading to further intrapulmonary dissemination. Significant signs or symptoms are frequent in locally progressive disease in children. High fever, severe cough with sputum production, weight loss, and night sweats are common. Physical signs include diminished breath sounds, rales, and dullness or egophony over the cavity. The prognosis for full but usually slow recovery is excellent with appropriate therapy.

REACTIVATION TUBERCULOSIS.

Pulmonary tuberculosis in adults usually represents endogenous reactivation of a site of tuberculosis infection established previously in the body. This form of tuberculosis is rare in childhood but may occur in adolescence. Children with a healed tuberculosis infection acquired before 2 yr of age rarely develop chronic reactivation pulmonary disease, which is more common in those who acquire the initial infection after 7 yr of age. The most frequent pulmonary sites are the original parenchymal focus, lymph nodes, or the apical seedings (Simon foci) established during the hematogenous phase of the early infection. This form of disease usually remains localized to the lungs because the established immune response prevents further extrapulmonary spread. The most common radiographic presentations of this type of tuberculosis are extensive infiltrates or thick-walled cavities in the upper lobes.

Older children and adolescents with reactivation tuberculosis are more likely to experience fever, anorexia, malaise, weight loss, night sweats, productive cough, hemoptysis, and chest pain than children with primary pulmonary tuberculosis. However, physical examination findings usually are minor or absent, even when cavities or large infiltrates are present. Most signs and symptoms improve within several weeks of starting effective treatment, although the cough may last for several months. This form of tuberculosis may be highly contagious if there is significant sputum production and cough. The prognosis for full recovery is excellent when patients are given appropriate therapy.

PLEURAL EFFUSION.

Tuberculous pleural effusions, which can be local or general, originate in the discharge of bacilli into the pleural space from a subpleural pulmonary focus or caseated lymph node. Asymptomatic local pleural effusion is so frequent in primary tuberculosis that it is basically a component of the primary complex. Larger and clinically significant effusions occur months to years after the primary infection. Tuberculous pleural effusion is infrequent in children <6 yr of age and rare in children <2 yr of age. Effusions are usually unilateral but can be bilateral. They are virtually never associated with a segmental pulmonary lesion and are rare in disseminated tuberculosis. Often the radiographic abnormality is more extensive than would be suggested by physical findings or symptoms (Fig. 197–4).

Clinical onset of tuberculous pleurisy is often sudden, characterized by low to high fever, shortness of breath, chest pain on deep inspiration, and diminished breath sounds. The fever and other symptoms may last for several weeks after the start of antituberculosis chemotherapy. The tuberculin skin test is positive in only 70–80% of cases. The prognosis is excellent, but radiographic resolution often takes months. Scoliosis is a rare complication from a long-standing effusion.

Figure 197-4 Pleural tuberculosis in a 16-yr-old girl.

Examination of pleural fluid and the pleural membrane is important to establish the diagnosis of tuberculous pleurisy. The pleural fluid is usually yellow and only occasionally tinged with blood. The specific gravity is usually 1.012–1.025, the protein level is usually 2–4?g/dL, and the glucose concentration may be low, although it is usually in the low-normal range (20–40?mg/dL). Typically there are several hundred to several thousand white blood cells per cubic millimeter with an early predominance of polymorphonuclear cells followed by a high percentage of lymphocytes. Acid-fast smears of the pleural fluid are rarely positive. Cultures of the fluid are positive in only <30% of cases. Biopsy of the pleural membrane is more likely to yield a positive acid-fast stain or culture, and granuloma formation usually can be demonstrated.

PERICARDIAL DISEASE.

The most common form of cardiac tuberculosis is pericarditis. It is rare, occurring in 0.5–4% of tuberculosis cases in children. Pericarditis usually arises from direct invasion or lymphatic drainage from subcarinal lymph nodes. The presenting symptoms are nonspecific, including low-grade fever, malaise, and weight loss. Chest pain is unusual in children. A pericardial friction rub or distant heart sounds with pulsus paradoxus may be present. The pericardial fluid is typically serofibrinous or hemorrhagic. Acid-fast smear of the fluid rarely reveals the organism, but cultures are positive in 30–70% of cases. The culture yield from pericardial biopsy may be higher, and the presence of granulomas often suggests the diagnosis. Partial or

complete pericardiectomy may be required when constrictive pericarditis develops.

LYMPHOHEMATOGENOUS (DISSEMINATED) DISEASE.

Tubercle bacilli are disseminated to distant sites, including liver, spleen, skin, and lung apices, in all cases of tuberculosis infection. The clinical picture produced by lymphohematogenous dissemination depends on the quantity of organisms released from the primary focus and the adequacy of the host immune response. Lymphohematogenous spread is usually asymptomatic. Rare patients experience protracted hematogenous tuberculosis caused by the intermittent release of tubercle bacilli as a caseous focus erodes through the wall of a blood vessel in the lung. Although the clinical picture may be acute, more often it is indolent and prolonged, with spiking fever accompanying the release of organisms into the bloodstream. Multiple organ involvement is common, leading to hepatomegaly, splenomegaly, lymphadenitis in superficial or deep nodes, and papulonecrotic tuberculids appearing on the skin. Bones and joints or kidneys also may become involved. Meningitis occurs only late in the course of the disease. Early pulmonary involvement is surprisingly mild, but diffuse involvement becomes apparent with prolonged infection.

The most clinically significant form of disseminated tuberculosis is miliary disease, which occurs when massive numbers of tubercle bacilli are released into the bloodstream, causing disease in two or more organs. Miliary tuberculosis usually complicates the primary infection, occurring within 2–6 mo of the initial infection. Although this form of disease is most common in infants and young children, it is also found in adolescents and older adults, resulting from the breakdown of a previously healed primary pulmonary lesion. The clinical manifestations of miliary tuberculosis are protean, depending on the load of organisms that disseminate and where they lodge. Lesions are often larger and more numerous in the lungs, spleen, liver, and bone marrow than other tissues. Because this form of tuberculosis is most common in infants and malnourished or immunosuppressed patients, the host's immune incompetency probably also plays a role in pathogenesis.

The onset of miliary tuberculosis is sometimes explosive, and the patient may become gravely ill in several days. More often, the onset is insidious with early systemic signs, including anorexia, weight loss, and low-grade fever. At this time abnormal physical signs are usually absent. Generalized lymphadenopathy and hepatosplenomegaly develop within several weeks in about 50% of cases. The fever may then become higher and more sustained, although the chest radiograph usually is normal and respiratory symptoms are minor or absent. Within several more weeks, the lungs may become filled with tubercles, and dyspnea, cough, rales, or wheezing occurs. The lesions of miliary tuberculosis are usually smaller than 2–3?mm in diameter when first visible on chest radiograph (Fig. 197–5). The smaller lesions coalesce to form larger lesions and sometimes extensive infiltrates. As the pulmonary disease progresses, an alveolar–air block syndrome may result in frank respiratory distress, hypoxia, and pneumothorax, or pneumomediastinum. Signs or symptoms of meningitis or peritonitis are found in 20–40% of patients with advanced disease. Chronic or recurrent headache in a patient with miliary tuberculosis usually indicates the presence of meningitis, whereas the onset of abdominal pain or tenderness is a sign of tuberculous peritonitis. Cutaneous lesions include papulonecrotic tuberculids, nodules, or purpura. Choroid tubercles occur in 13–87% of patients and are highly specific for the diagnosis of miliary tuberculosis. Unfortunately, the tuberculin skin test is nonreactive in up to 40% of patients with disseminated tuberculosis.

Diagnosis of disseminated tuberculosis can be difficult, and a high index of suspicion by the clinician is required. Often the patient presents with fever of unknown origin. Early sputum or gastric aspirate cultures have a low sensitivity. Biopsy of the liver or bone marrow with appropriate bacteriologic and histologic

Figure 197-5 Posteroanterior *(A)* and lateral *(B)* chest radiographs of an infant with miliary tuberculosis. The child's mother had failed to complete treatment for pulmonary tuberculosis twice within 3 yr of this child's birth.

examinations more often yields an early diagnosis. The most important clue is usually history of recent exposure to an adult with infectious tuberculosis.

The resolution of miliary tuberculosis is slow, even with proper therapy. Fever usually declines within 2–3 wk of starting chemotherapy, but the chest radiographic abnormalities may not resolve for many months. Occasionally, corticosteroids hasten symptomatic relief, especially when air block, peritonitis, or meningitis is present. The prognosis is excellent if the diagnosis is made early and adequate chemotherapy is given.

UPPER RESPIRATORY TRACT DISEASE.

Tuberculosis of the upper respiratory tract is rare in developed countries but is still observed in developing countries. Children with laryngeal tuberculosis have a croupy cough, sore throat, hoarseness, and dysphagia. Most children with laryngeal tuberculosis have extensive upper lobe pulmonary disease, but occasional patients have primary laryngeal disease with a normal chest radiograph. Tuberculosis of the middle ear results from aspiration of infected pulmonary secretions into the middle ear or from hematogenous dissemination in older children. The most common signs and symptoms are painless unilateral otorrhea, tinnitus, decreased hearing, facial paralysis, and a perforated tympanic membrane. Enlargement of lymph nodes in the preauricular or anterior cervical chains may accompany this infection. Diagnosis is difficult because stains and cultures of ear fluid are frequently negative and histology of the affected tissue often shows a nonspecific acute and chronic inflammation without granuloma formation.

LYMPH NODE DISEASE.

Tuberculosis of the superficial lymph nodes, often referred to as scrofula, is the most common form of extrapulmonary tuberculosis in children. Historically, scrofula was usually caused by drinking unpasteurized cow's milk laden with *M. bovis*. Most current cases occur within 6–9 mo of initial infection by *M. tuberculosis*, although some cases appear years later. The tonsillar, anterior cervical, submandibular, and supraclavicular nodes become involved secondary to extension of a primary lesion of the upper lung fields or abdomen. Infected nodes in the inguinal, epitrochlear, or axillary regions result from regional lymphadenitis associated with tuberculosis of the

skin or skeletal system. The nodes usually enlarge gradually in the early stages of lymph node disease. They are firm but not hard, discrete, and nontender. The nodes often feel fixed to underlying or overlying tissue. Disease is most often unilateral, but bilateral involvement may occur because of the crossover drainage patterns of lymphatic vessels in the chest and lower neck. As infection progresses, multiple nodes are infected, resulting in a mass of matted nodes. Systemic signs and symptoms other than a low-grade fever are usually absent. The tuberculin skin test is usually reactive. The chest radiograph is normal in 70% of cases. The onset of illness is occasionally more acute, with rapid enlargement of lymph nodes, high fever, tenderness, and fluctuance. The initial presentation is rarely a fluctuant mass with overlying cellulitis or skin discoloration.

Lymph node tuberculosis may resolve if left untreated but more often progresses to caseation and necrosis. The capsule of the node breaks down, resulting in the spread of infection to adjacent nodes. Rupture of the node usually results in a draining sinus tract that may require surgical removal. Tuberculous lymphadenitis usually responds well to antituberculosis therapy, although the lymph nodes do not return to normal size for months or even years. Surgical removal alone is not adequate therapy because the lymph node disease is but one part of a systemic infection.

A definitive diagnosis of tuberculous adenitis usually requires histologic or bacteriologic confirmation, which is best accomplished by excisional biopsy of the involved node. Culture of lymph node tissue yields the organism in only about 50% of cases. Many other conditions can be confused with tuberculous adenitis, including infection due to NTM, cat-scratch disease (*Bartonella henselae*), tularemia, brucellosis, toxoplasmosis, tumor, branchial cleft cyst, cystic hygroma, and pyogenic infection. The most frequent problem is distinguishing infection due to *M. tuberculosis* from lymphadenitis due to NTM in geographic areas where NTM are common. Both conditions are usually associated with a normal chest radiograph and a reactive tuberculin skin test. An important clue to the diagnosis of tuberculous adenitis is an epidemiologic link to an adult with infectious tuberculosis. In areas where both diseases are common, the only way to distinguish them may be culture of the involved tissue.

CENTRAL NERVOUS SYSTEM DISEASE.

Tuberculosis of the central nervous system is the most serious complication in children and is fatal without effective treatment. Tuberculous meningitis usually arises from the formation of a metastatic caseous lesion in the cerebral cortex or meninges that develops during the lymphohematogenous dissemination of the primary infection. This initial lesion increases in size and discharges small numbers of tubercle bacilli into the subarachnoid space. The resulting gelatinous exudate infiltrates the corticomeningeal blood vessels, producing inflammation, obstruction, and subsequent infarction of cerebral cortex. The brainstem is often the site of greatest involvement, which accounts for the frequently associated dysfunction of cranial nerves III, VI, and VII. The exudate also interferes with the normal flow of cerebrospinal fluid (CSF) in and out of the ventricular system at the level of the basilar cisterns, leading to a communicating hydrocephalus. The combination of vasculitis, infarction, cerebral edema, and hydrocephalus results in the severe damage that can occur gradually or rapidly. Profound abnormalities in electrolyte metabolism, due to salt wasting or the syndrome of inappropriate antidiuretic hormone secretion, also contribute to the pathophysiology of tuberculous meningitis.

Tuberculous meningitis complicates about 0.3% of untreated tuberculosis infections in children. It is most common in children between 6 mo and 4 yr of age. Occasionally, tuberculous meningitis occurs many years after the infection, when rupture of one or more of the subependymal tubercles discharges tubercle bacilli into the subarachnoid space. The clinical progression of tuberculous meningitis may be rapid or gradual. Rapid progression tends to occur more often in infants and young children, who may experience symptoms for only several days before the onset of acute hydrocephalus, seizures, and cerebral edema. More commonly, the signs and symptoms progress slowly over several weeks and can be divided into three stages. The first stage, which typically lasts 1–2 wk, is characterized by nonspecific symptoms, such as fever, headache, irritability, drowsiness, and malaise. Focal neurologic signs are absent, but infants may experience a stagnation or loss of developmental milestones. The second stage usually begins more abruptly. The most common features are lethargy, nuchal rigidity, seizures, positive Kernig or Brudzinski signs, hypertonia, vomiting, cranial nerve palsies, and other focal neurologic signs. The accelerating clinical illness usually correlates with the development of hydrocephalus, increased intracranial pressure, and vasculitis. Some children have no evidence of meningeal irritation but may have signs of encephalitis, such as disorientation, movement disorders, or speech impairment. The third stage is marked by coma, hemiplegia or paraplegia, hypertension, decerebrate posturing, deterioration of vital signs, and, eventually, death. The prognosis of tuberculous meningitis correlates most closely with the clinical stage of illness at the time treatment is initiated. The majority of patients in the first stage have an excellent outcome, whereas most patients in the third stage who survive have permanent disabilities, including blindness, deafness, paraplegia, diabetes insipidus, or mental retardation. The prognosis for young infants is generally worse than for older children. It is imperative that antituberculosis treatment be considered for any child who develops basilar meningitis and hydrocephalus, cranial nerve palsy, or stroke with no other apparent etiology. Often the key to the correct diagnosis is identifying an adult in

contact with the child who has infectious tuberculosis. Because of the short incubation period of tuberculous meningitis, the ill adult has not yet been diagnosed in many cases.

The diagnosis of tuberculous meningitis can be difficult early in its course, requiring a high degree of suspicion on the part of the clinician. The tuberculin skin test is nonreactive in up to 50% of cases and 20–50% of children have a normal chest radiograph. The most important laboratory test for the diagnosis of tuberculous meningitis is examination and culture of the lumbar CSF. The CSF leukocyte count usually ranges from 10–500 cells/mm^3 . Polymorphonuclear leukocytes may be present initially, but lymphocytes predominate in the majority of cases. The CSF glucose is typically <40?mg/dL but rarely <20?mg/dL. The protein level is elevated and may be markedly high (400–5,000?mg/dL) secondary to hydrocephalus and spinal block. Although the lumbar CSF is grossly abnormal, ventricular CSF may have normal chemistries and cell counts because this fluid is obtained from a site proximal to the inflammation and obstruction. The success of the microscopic

examination of acid-fast stained CSF and mycobacterial culture is related directly to the volume of the CSF sample. Examinations or culture of small amounts of CSF are unlikely to demonstrate *M. tuberculosis*. When 5–10?mL of lumbar CSF can be obtained, the acid-fast stain of the CSF sediment is positive in up to 30% of cases and the culture is positive in 50–70% of cases. Cultures of other fluids, such as gastric aspirates or urine, may help confirm the diagnosis. Radiographic studies may aid in the diagnosis of tuberculous meningitis. CT or MRI of the brain of patients with tuberculous meningitis may be normal during early stages of the disease. As disease progresses, basilar enhancement and communicating hydrocephalus with signs of cerebral edema or early focal ischemia are the most common findings. Some small children with tuberculous meningitis may have one or several clinically silent tuberculomas, occurring most often in the cerebral cortex or thalamic regions.

Another manifestation of central nervous system tuberculosis is the **tuberculoma**, which usually presents clinically as a brain tumor. Tuberculomas account for up to 40% of brain tumors in some areas of the world, but they are rare in North America. In adults tuberculomas are most often supratentorial, but in children they are often infratentorial, located at the base of the brain near the cerebellum. Lesions are most often singular but may be multiple. The most common symptoms are headache, fever, and convulsions. The tuberculin skin test is usually reactive, but the chest radiograph is usually normal. Surgical excision is often necessary to distinguish tuberculoma from other causes of brain tumor. However, surgical removal is not necessary because most tuberculomas resolve with medical management. Corticosteroids are usually administered during the first few weeks of treatment or in the immediate postoperative period to decrease cerebral edema. On CT or MRI of the brain, tuberculomas usually appear as discrete lesions with a significant amount of surrounding edema. Contrast medium enhancement is often impressive and may result in a ringlike lesion. Since the advent of CT, the paradoxical development of tuberculomas in patients with tuberculous meningitis who are receiving ultimately effective chemotherapy has been recognized. The cause and nature of these tuberculomas are poorly understood, but they do not represent failure of drug treatment. This phenomenon should be considered whenever a child with tuberculous meningitis deteriorates or develops focal neurologic findings while on treatment. Corticosteroids may help alleviate the occasionally severe clinical signs and symptoms that occur. These lesions may persist for months or even years.

CUTANEOUS DISEASE.

Cutaneous tuberculosis is rare in the United States but occurs worldwide and accounts for 1–2% of tuberculosis (Chapter 655).

BONE AND JOINT DISEASE.

Bone and joint infection complicating tuberculosis is most likely to involve the vertebrae. The classic manifestation of tuberculous spondylitis is progression to Pott disease, in which destruction of the vertebral bodies leads to gibbus deformity and kyphosis (Chapter 669.4). Skeletal tuberculosis is a late complication of tuberculosis and although it has become a rare entity since antituberculosis therapy became available, it is more likely to occur in children than in adults. Tuberculous bone lesions may resemble pyogenic and fungal infections, or bone tumors. Multifocal bone involvement can occur. A bone biopsy is essential to confirm the diagnosis.

ABDOMINAL AND GASTROINTESTINAL DISEASE.

Tuberculosis of the oral cavity or pharynx is quite unusual. The most common lesion is a painless ulcer on the mucosa, palate, or tonsil with enlargement of the regional lymph nodes. Tuberculosis of the parotid gland has been reported rarely in endemic countries. Tuberculosis of the esophagus is rare in children but may be associated with a tracheoesophageal fistula in infants. These forms of tuberculosis are usually associated with extensive pulmonary disease and swallowing of infectious respiratory secretions. However, they can occur in the absence of pulmonary disease, presumably by spread from mediastinal or peritoneal lymph nodes.

Tuberculous peritonitis, which occurs most often in young men, is uncommon in adolescents and rare in children. Generalized peritonitis may arise from subclinical or miliary hematogenous dissemination. Localized peritonitis is caused by direct extension from an abdominal lymph node, intestinal focus, or genitourinary tuberculosis. Rarely, the lymph nodes, omentum, and peritoneum become matted and can be palpated as a “doughy” irregular nontender mass. Abdominal pain or tenderness, ascites, anorexia and low-grade fever are typical manifestations. The tuberculin skin test is usually reactive. The diagnosis can be confirmed by paracentesis with appropriate stains and cultures, but this procedure must be performed carefully to avoid entering a bowel that is intertwined with the matted omentum.

Tuberculous enteritis is caused by hematogenous dissemination or by swallowing tubercle bacilli discharged from the patient's own lungs. The jejunum and ileum near Peyer patches and the appendix are the most common sites of involvement. The typical findings are shallow ulcers that cause pain, diarrhea or constipation, and weight loss with low-grade fever. Mesenteric adenitis usually complicates the infection. The enlarged nodes may cause intestinal obstruction or erode through the omentum to cause generalized peritonitis. The clinical presentation of tuberculous enteritis is nonspecific, mimicking other infections and conditions that cause diarrhea. The disease should be suspected in any child with chronic gastrointestinal complaints and a reactive tuberculin skin test. Biopsy, acid-fast stain, and culture of the lesions are usually necessary to confirm the diagnosis.

GENITOURINARY DISEASE.

Renal tuberculosis is rare in children because the incubation period is several years or longer. Tubercle bacilli usually reach the kidney during lymphohematogenous dissemination. The organisms often can be recovered from the urine in cases of miliary tuberculosis and in some patients with pulmonary tuberculosis in the absence of renal parenchymal disease. In true renal tuberculosis, small caseous foci develop in the renal parenchyma and release *M. tuberculosis* into the tubules. A large mass develops near the renal cortex that discharges bacteria through a fistula into the renal pelvis. Infection then spreads locally to the ureters, prostate, or epididymis. Renal tuberculosis is often clinically silent in its early stages, marked only by sterile pyuria and microscopic hematuria. Dysuria, flank or abdominal pain, and gross hematuria develop as the disease progresses. Superinfection by other bacteria, which often causes more acute symptoms, occurs frequently but may also delay

recognition of the underlying tuberculosis. Hydronephrosis or ureteral strictures may complicate the disease. Urine cultures for *M. tuberculosis* are positive in 80–90% of cases, and acid-fast stains of large volumes of urine

sediment are positive in 50–70% of cases. The tuberculin skin test is nonreactive in up to 20% of patients. An intravenous pyelogram often reveals mass lesions, dilatation of the proximal ureters, multiple small filling defects, and hydronephrosis if ureteral stricture is present. Disease is most often unilateral.

Tuberculosis of the genital tract is uncommon in both males and females before puberty. This condition usually originates from lymphohematogenous spread, although it can be caused by direct spread from the intestinal tract or bone. Adolescent girls may develop genital tract tuberculosis during the primary infection. The fallopian tubes are most often involved (90–100% of cases) followed by the endometrium (50%), ovaries (25%), and cervix (5%). The most common symptoms are lower abdominal pain and dysmenorrhea or amenorrhea. Systemic manifestations are usually absent and the chest radiograph is normal in the majority of cases. The tuberculin skin test is usually reactive. Genital tuberculosis in adolescent males causes epididymitis or orchitis. The condition usually manifests as a unilateral nodular painless swelling of the scrotum. Involvement of the glans penis is extremely rare. Genital abnormalities and a positive tuberculin skin test in an adolescent male or female should suggest the diagnosis of genital tract tuberculosis.

DISEASE IN HIV-INFECTED CHILDREN.

Most cases of tuberculosis in HIV-infected children have been described in developing countries. The rate of tuberculosis disease in HIV-infected children is 30 times higher than in non–HIV-infected children in the United States. Establishing the diagnosis of tuberculosis in an HIV-infected child may be difficult because skin test reactivity can be absent, culture confirmation is difficult, and the clinical features of tuberculosis are similar to many other HIV-related infections and conditions. Tuberculosis in HIV-infected children is often more severe, progressive, and likely to occur in extrapulmonary sites. Radiographic findings are similar to those in children with normal immune systems, but lobar disease and lung cavitation are more common. Nonspecific respiratory symptoms, fever, and weight loss are the most common complaints. Rates of drug-resistant tuberculosis are higher in HIV-infected adults and, probably, are also higher in HIV-infected children. The mortality rate of HIV-infected children with tuberculosis is high, especially as the CD4 lymphocyte numbers decrease. In adults, the host immune response to tuberculosis infection appears to enhance HIV replication and accelerate the immune suppression caused by HIV. Increased mortality rates are attributed to progressive HIV infection rather than tuberculosis. Therefore, HIV-infected children with potential exposures and/or recent infection should be promptly evaluated and treated for tuberculosis. Conversely, all children with tuberculosis disease should be tested for HIV co-infection, because of the potential benefits of early diagnosis and treatment of HIV infection, and because the presence of HIV may necessitate a longer duration of treatment.

PERINATAL DISEASE.

Symptoms of congenital tuberculosis may be present at birth but more commonly begin by the 2nd or 3rd wk of life. The most common signs and symptoms are respiratory distress, fever, hepatic or splenic enlargement, poor feeding, lethargy or irritability, lymphadenopathy, abdominal distention, failure to thrive, ear drainage, and skin lesions. The clinical manifestations vary in relation to the site and size of the caseous lesions. Many infants have an abnormal chest radiograph, most often a miliary pattern. Some infants with no pulmonary findings early in the course of the disease later develop profound radiographic and clinical abnormalities. Hilar and mediastinal lymphadenopathy and lung infiltrates are common. Generalized lymphadenopathy and meningitis occur in 30–50% of patients.

The clinical presentation of tuberculosis in newborns is similar to that caused by bacterial sepsis and other congenital infections, such as syphilis, toxoplasmosis, and cytomegalovirus. The diagnosis should be suspected in an infant with signs and symptoms of bacterial or congenital infection whose response to antibiotic and supportive therapy is poor and evaluation for other infections is unrevealing. The most important clue for rapid diagnosis of congenital tuberculosis is a maternal or family history of tuberculosis. Frequently, the mother's disease is discovered only after the neonate's diagnosis is suspected. The infant's tuberculin skin test is negative initially but may become positive in 1–3 mo. A positive acid-fast stain of an early morning gastric aspirate from a newborn usually indicates tuberculosis. Direct acid-fast stains on middle-ear discharge, bone marrow, tracheal aspirate, or biopsy tissue (especially liver) can be useful. The CSF should be examined and cultured, although the yield for isolating *M. tuberculosis* is low. The mortality rate of congenital tuberculosis remains very high because of delayed diagnosis; many children will have a complete recovery if the diagnosis is made promptly and adequate chemotherapy is started.

Treatment.

Tubercle bacilli can be killed only during replication. Individual organisms that are naturally resistant to each antimycobacterial drug are present within large populations of *M. tuberculosis*. All known genes that encode for drug resistance within *M. tuberculosis* are located on a chromosome; transfer between organisms does not occur. The estimated frequency of these naturally drug-resistant organisms is about 10^{-6} but varies among drugs: with streptomycin (STM) it is 10^{-5} ; with isoniazid (INH), 10^{-6} ; with rifampin (RIF), 10^{-8} . A cavity containing 10^{9} tubercle bacilli has thousands of drug-resistant organisms, whereas a closed caseous lesion with its much smaller population contains few, if any, naturally resistant organisms. Fortunately, the natural occurrence of resistance to one drug is independent of resistance to any other drug. The chance that an organism is naturally resistant to both INH and RIF is on the order of 10^{-14} . Because populations of this size do not occur in patients, organisms naturally resistant to two drugs are essentially nonexistent.

The major biologic determinant of the success of antituberculosis chemotherapy is the size of the bacillary population within the host. For patients with large bacterial populations, such as adults with cavities or extensive infiltrates, many naturally

drug-resistant organisms are present and at least two antituberculosis drugs must be used to achieve cure. Conversely, for patients with infection (reactive skin test) but no disease, the bacterial population is small, drug-resistant organisms are rare or nonexistent, and a single drug can be used. Children with pulmonary tuberculosis and most patients with extrapulmonary tuberculosis have medium-sized populations in which significant numbers of naturally drug-resistant organisms may or may not be present. In general, these patients are treated with at least two drugs. The phenomena of drug resistance mutation and microbial population size explain why poor patient adherence to treatment or an inadequate treatment regimen can lead to the development of drug-resistant tuberculosis. If a patient with extensive pulmonary tuberculosis is given a single medication, the subpopulation of bacilli susceptible to that drug will be eliminated but the subpopulation of bacilli resistant to the drug have the opportunity to multiply and become the predominant strain. The patient will temporarily improve but will suffer a relapse from tuberculosis completely resistant to that drug. With treatment using two drugs to which the *M. tuberculosis* isolate is susceptible, drug X eliminates the subpopulation of bacilli resistant to drug Y, and drug Y eliminates the subpopulation of bacilli resistant to drug X. If all the organisms have initial resistance to a certain medication (called primary resistance) and the patient is treated with that plus one other medication, only one effective medication is being used and the patient will eventually relapse with tuberculosis that is resistant to both drugs.

The various antituberculosis drugs (Table 197–1) differ in their primary site of activity and their actions. INH and RIF are highly bactericidal for *M. tuberculosis*. STM and several other aminoglycoside antibiotics are also bactericidal for extracellular

TABLE 197-1 -- Most Commonly Used Antituberculosis Drugs

Drug	Daily Dose (mg/kg/24?hr)	Twice-Weekly Dose (mg/kg/dose)	Maximum Dose
Isoniazid*	10–15	20–30	Daily: 300?mg; twice weekly: 900?mg
Rifampin*	10–20	10–20	600?mg
Pyrazinamide*	20–40	40–60	2?g
Streptomycin (IM)	20–40	20–40	1?g
Ethambutol	15–25	25–50	2.5?g
Ethionamide	15–20 (1–3 divided doses)	—	1?g
Cycloserine	10–20 (1–2 divided doses)	—	1?g
Kanamycin or capreomycin (IM)	15–30	15–30	1?g
Amikacin (IV)	15–30	15–30	1?g

IM = intramuscular; IV = intravenous.

**Isoniazid (150?mg) and rifampin (300?mg) are combined in one preparation called Rifamate. Isoniazid (50?mg), rifampin (120?mg), and pyrazinamide (300?mg) are combined in one preparation called Rifater.*

tubercle bacilli, but their penetration into macrophages is poor. Pyrazinamide (PZA) cannot be shown to be bactericidal in the laboratory but clearly contributes to the killing of *M. tuberculosis* within the patient. Other antituberculosis drugs, such as ethambutol (EMB) at low doses (15?mg/kg/24?hr), ethionamide (ETH), and cycloserine, are bacteriostatic for *M. tuberculosis* and their primary purpose in the therapeutic regimen is to prevent emergence of resistance to other drugs. EMB at 25?mg/kg/24?hr has some bactericidal activity, which may be important in treating cases of drug-resistant tuberculosis. INH, RIF, and EMB are also effective in preventing emergence of resistance to other drugs, but pyrazinamide has almost no similar activity.

ISONIAZID.

INH is inexpensive, diffuses into all tissues and body fluids, and has a very low rate of adverse reactions in children. It can be administered either orally or intramuscularly. At the usual daily dose of 10?mg/kg, serum concentrations greatly exceed the minimum inhibitory concentration for *M. tuberculosis*. Peak concentrations in blood, sputum, and CSF are reached within a few hours and persist for at least 6–8?hr. INH is metabolized by acetylation in the liver. Rapid acetylation is more frequent among African-Americans and Asians than among whites. There is no correlation between acetylation rate and either efficacy or adverse reactions in children.

INH has two principal toxic effects, both of which are rare in children. Peripheral neuritis results from competitive inhibition of pyridoxine utilization. Pyridoxine levels are decreased in children taking INH, but clinical manifestations are rare and pyridoxine administration is not generally recommended. However, teenagers with inadequate diets, children from groups with low levels of milk and meat intake, symptomatic HIV-infected children, and breast-feeding infants require supplemental pyridoxine. The most common physical manifestation of peripheral neuritis is numbness and tingling in the hands or feet. CNS toxicity from INH is rare, occurring usually when there is a significant overdose. The major toxic effect of INH is hepatotoxicity. As many as 3–10% of children taking INH experience transient elevated serum transaminase levels. Clinically significant hepatotoxicity is rare, being more likely to occur in adolescents or in children with severe forms of tuberculosis or underlying liver disease. For most children, routine biochemical monitoring is not necessary, and toxicity can be monitored using clinical signs and symptoms. Early manifestations include nausea, vomiting, abdominal pain, and jaundice. Serum transaminase levels usually normalize with discontinuation of INH. Allergic or hypersensitivity reactions caused by INH are rare. INH can increase phenytoin levels and lead to toxicity by blocking its metabolism. Occasionally, INH interacts with theophylline, requiring modification of the dosage. Rare side effects of INH include pellagra, hemolytic anemia in patients with glucose-6-phosphate dehydrogenase

deficiency, and a lupus-like reaction with rash and arthritis.

RIFAMPIN.

RIF is well absorbed from the gastrointestinal tract during fasting, with peak serum levels achieved within 2?hr. Oral and intravenous forms of RIF are available. Like INH, rifampin is distributed widely in tissues and body fluids, including the CSF, and it is metabolized by the liver. Whereas excretion is mainly through the biliary tract, effective levels are reached in the kidneys and urine. Side effects are more common than with INH and include orange discoloration of urine and tears (with permanent staining of contact lenses), gastrointestinal disturbances, and hepatotoxicity, usually manifested as asymptomatic elevations in serum transaminase levels. When RIF is administered with INH, there is an increased risk of hepatotoxicity, which can be minimized by lowering the daily dose of INH to 10?mg/kg/24?hr. Severe hepatotoxicity has been reported in adults treated with combination of RIF and PZA, but not in children. RIF has been associated with thrombocytopenia and influenza-like syndrome. It can render oral contraceptives ineffective and interacts with several drugs, including quinidine, cyclosporine, sodium warfarin, protease inhibitors, non-nucleoside reverse-transcriptase inhibitors, and corticosteroids. RIF is generally available in 150?mg and 300?mg capsules that, unfortunately, are inconvenient for many weight ranges of children. A suspension can be made using a variety of carriers but should not be taken with food because of malabsorption. A fixed combination preparation, Rifamate, contains both INH (150?mg) and RIF (300?mg); this preparation helps to ensure that the patient receives both INH and RIF so that selective drug resistance is not created.

PYRAZINAMIDE.

In adults, a once-daily dose of PZA, 30?mg/ kg/24?hr, produces serum levels of 20?µg/mL and little liver toxicity. The optimal dose in children is unknown, but this same dose causes high CSF levels, is well tolerated by children, and correlates with clinical success in treatment trials of tuberculosis in children. Extensive experience with PZA in children has verified its safety. Approximately 10% of adults treated with PZA develop arthralgias, arthritis, or gout due to hyperuricemia. Although uric acid levels are slightly elevated in children taking PZA, clinical manifestations of the hyperuricemia are extremely rare. Hypersensitivity reactions are rare in children. The only dosage form of PZA is a rather large 500-mg tablet, which produces some dosing problems for children, especially infants. These pills can be crushed and given with food in the same manner as INH, but formal pharmacokinetic studies using this method have not been reported. A fixed combination preparation, Rifater, contains INH (50?mg), RIF (120?mg), and PZA (300?mg).

STREPTOMYCIN.

STM is used less frequently than in the past for the treatment of childhood tuberculosis but is important

for the treatment of drug-resistant disease. It may be given intramuscularly or intravenously. Pain and induration at the injection site are common after intramuscular administration. STM penetrates inflamed meninges fairly well but does not cross uninflamed meninges. Its major current use is when initial INH resistance is suspected or when the child has a life-threatening form of tuberculosis. The major toxicity of STM is dose-related damage to the vestibular and auditory portions of the 8th cranial nerve. Renal toxicity is much less frequent. STM is contraindicated in pregnant women because up to 30% of their infants will suffer severe hearing loss.

ETHAMBUTOL.

EMB has received little attention in children because of its potential toxicity to the eye. At a dose of 15?mg/kg/24?hr it is primarily bacteriostatic, and its historic purpose has been to prevent emergence of resistance to other drugs. However, at 25?mg/kg/24?hr, EMB has some bactericidal activity, which may be important in the treatment of drug-resistant disease. It is well tolerated by both adults and children when given orally as a once- or twice-a-day dose. The major potential toxicity is optic neuritis and red-green color blindness. There have been no reports of optic toxicity in children, but the drug has not been widely used because of the inability to routinely test visual fields and acuity in young children. EMB is not recommended for general use in young children for whom vision cannot be adequately examined but should be considered for children with suspected drug-resistant tuberculosis when other agents are not available or cannot be used.

ETHIONAMIDE.

ETH is a bacteriostatic drug whose major purpose is treatment of drug-resistant tuberculosis. ETH penetrates into CSF very well and may be particularly useful in cases of tuberculous meningitis. It is generally well tolerated by children but often must be given in two or three divided daily doses because of gastrointestinal disturbance. ETH is chemically similar to INH and can cause significant hepatitis.

OTHER DRUGS.

These drugs are used less commonly for tuberculosis because they are significantly less effective or more toxic. Several aminoglycosides, especially kanamycin and amikacin, have significant antituberculosis activity and are used in cases of streptomycin-resistant tuberculosis. A closely related drug, capreomycin, is used more commonly in adults. These drugs can be given either intramuscularly or intravenously, are bactericidal, and usually do not demonstrate cross resistance with STM. Cycloserine is an effective antituberculosis drug in adults but has been used infrequently in children because of its major side effects of impairment with thought processes and tendency to cause depression and other psychiatric abnormalities. The drug is usually given in one or two divided doses, and most experts recommend monitoring serum levels during administration. Pyridoxine supplementation should be given when cycloserine is used. Ciprofloxacin and ofloxacin are quinolones with significant antituberculosis activity that are used commonly for drug-resistant tuberculosis in adults. These drugs are generally contraindicated in children because they cause destruction of growing cartilage in some animal models. However, they have been used effectively in some cases of multidrug-resistant tuberculosis in

children when few other effective agents were available.

TREATMENT REGIMENS FOR DISEASE.

The basic principles of management of tuberculosis disease in children and adolescents are the same as those in adults. Several drugs are used to effect a relatively rapid cure and prevent the emergence of secondary drug resistance during therapy. The choice of regimen depends on the extent of tuberculosis disease, the host, and the likelihood of drug resistance. The standard therapy of intrathoracic tuberculosis (pulmonary disease and/or hilar lymphadenopathy) in children, recommended by the CDC and AAP, is a 6 mo regimen of INH and RIF supplemented in the first 2 mo of treatment by PZA. Several clinical trials have shown that this regimen yields a success rate approaching 100% with an incidence of clinically significant adverse reactions of <2%. A regimen of INH and RIF for 9 mo is also highly effective for drug-susceptible tuberculosis, but the necessary length of treatment, the need for good adherence by the patient, and the relative lack of protection against possible initial drug resistance have led to the use of shorter regimens. Most experts recommend that all drug administration be directly observed, meaning that a health care worker is physically present when the medications are administered to the patients. When directly observed therapy is used, intermittent (twice-weekly) administration of drugs after an initial period as short as 2 wk of daily therapy is as effective in children as daily therapy for the entire course. In locales where the community rate of INH resistance is greater than 5–10%, or when the adult source case is at increased risk for drug-resistant tuberculosis, most experts recommend adding a fourth drug—usually STM, EMB, or ETH—to the initial regimen. The reason to add the fourth drug is that PZA is not effective in preventing the emergence of RIF resistance during therapy when INH resistance already exists.

Controlled clinical trials for treating various forms of extrapulmonary tuberculosis are virtually nonexistent. Extrapulmonary tuberculosis is usually caused by small numbers of mycobacteria. In general, the treatment for most forms of extrapulmonary tuberculosis in children, including cervical lymphadenopathy, is the same as for pulmonary tuberculosis. Exceptions are bone and joint, disseminated, and CNS tuberculosis for which there are inadequate data to recommend 6-mo therapy. These cases usually are treated for 9–12 mo. Surgical debridement in bone and joint disease and ventriculoperitoneal shunting in CNS disease are frequently necessary.

The optimal treatment of tuberculosis in HIV-infected children has not been established. HIV seropositive adults with tuberculosis can be treated successfully with standard regimens that include INH, RIF, and PZA. The total duration of therapy should be 6–9 mo, or 6 mo after culture of sputum becomes sterile, whichever is longer. Data for children are limited to isolated case reports and small series. Most experts believe that HIV-seropositive children with drug-susceptible tuberculosis should receive at least three drugs such as INH, RIF, and PZA for the first 2 mo followed by INH and RIF for a total duration of at least 9 mo. A fourth drug such as ETM or STM should be added for disseminated disease and when drug-resistance is suspected. Rifampin resistant tuberculosis is more common in HIV-infected patients. Children with HIV infection appear to have more frequent adverse reactions to antituberculosis drugs and must be monitored closely during therapy. Coadministration of rifampin and some antiretroviral agents results in subtherapeutic blood levels of protease inhibitors and non-nucleoside reverse transcriptase inhibitors, and toxic levels of rifampin. Concomitant administration of these drugs is not recommended. Treatment of HIV infected children is often empirical based on epidemiologic and radiographic information, because the radiographic appearance of other pulmonary complications of HIV in children, such as lymphoid interstitial pneumonitis and bacterial pneumonia, may be similar to that of tuberculosis. Therapy should be considered when tuberculosis cannot be excluded.

DRUG-RESISTANT TUBERCULOSIS.

The incidence of drug-resistant tuberculosis is increasing in many areas of the world, including North America. There are two major types of drug resistance. Primary resistance occurs when an individual is infected with *M. tuberculosis* that is already resistant to a particular drug. Secondary resistance occurs when drug-resistant organisms emerge as the dominant population during treatment. The major causes of secondary drug resistance are poor adherence with the medication by the patient or inadequate treatment regimens prescribed by the physician. Nonadherence with one drug is more likely to lead to secondary resistance than failure to take all drugs. Secondary resistance is rare in children because of the small size

of their mycobacterial population. Therefore, most drug resistance in children is primary, and patterns of drug resistance among children tend to mirror those found among adults in the same population. The main predictors of drug-resistant tuberculosis among adults are history of previous antituberculosis treatment, co-infection with HIV, and exposure to another adult with infectious drug-resistant tuberculosis.

Treatment of drug-resistant tuberculosis is successful only when at least two bactericidal drugs are given to which the infecting strain of *M. tuberculosis* is susceptible. When a child has possible drug-resistant tuberculosis, at least three and usually four or five drugs should be administered initially until the susceptibility pattern is determined and a more specific regimen can be designed. The specific treatment plan must be individualized for each patient according to the results of susceptibility testing on the isolates from the child or the adult source case. Treatment duration of 9 mo with RIF, PZA, and EMB is usually adequate for INH-resistant tuberculosis in children. When resistance to INH and RIF is present, the total duration of therapy often must be extended to 12–18 mo, and twice-a-week regimens should not be used. The prognosis of single- or multidrug-resistant tuberculosis in children is usually good if the drug resistance is identified early in the treatment, appropriate drugs are administered under directly observed therapy, adverse reactions from the drugs do not occur, and the child and family are in a supportive environment. The treatment of drug-resistant tuberculosis in children always should be undertaken by a clinician with specific expertise in the treatment of tuberculosis.

CORTICOSTEROIDS.

These are useful in the treatment of some children with tuberculosis disease. They are most beneficial when the host inflammatory reaction contributes significantly to

tissue damage or impairment of organ function. There is convincing evidence that corticosteroids decrease mortality rates and long-term neurologic sequelae in some patients with tuberculous meningitis by reducing vasculitis, inflammation, and ultimately, intracranial pressure. Lowering the intracranial pressure limits tissue damage and favors circulation of antituberculosis drugs through the brain and meninges. Short courses of corticosteroids also may be effective for children with endobronchial tuberculosis that causes respiratory distress, localized emphysema, or segmental pulmonary lesions. Several randomized clinical trials have shown that corticosteroids can help relieve symptoms and constriction associated with acute tuberculous pericardial effusion. Corticosteroids may cause dramatic improvement in symptoms in some patients with tuberculous pleural effusion and shift of the mediastinum. However, the long-term course of disease is probably unaffected. Some children with severe miliary tuberculosis have dramatic improvement with corticosteroid therapy if the inflammatory reaction is so severe that alveolocapillary block is present. There is no convincing evidence that one corticosteroid preparation is better than another. The most commonly prescribed regimen is prednisone, 1–2?mg/kg/24?hr in one to two divided doses orally for 4–6 wk, followed by gradual tapering.

SUPPORTIVE CARE.

Children receiving treatment should be followed carefully to promote adherence with therapy, to monitor for toxic reactions to medications, and to ensure that the tuberculosis is being adequately treated. Adequate nutrition is important. Patients should be seen at monthly intervals and should be given just enough medication to last until the next visit. Anticipatory guidance with regard to the administration of medications to children is crucial. The physician should foresee difficulties that the family might have in introducing several new medications in inconvenient dosage forms to a young child. The clinician must report all cases of suspected tuberculosis in a child to the local health department to be sure that the child and family receive appropriate care and evaluation.

Nonadherence to treatment is the major problem in tuberculosis therapy. The patient and family must know what is expected of them through verbal and written instructions in their primary language. From 30–50% of patients taking long-term treatment are significantly nonadherent with self-administered medications, and clinicians are usually not able to determine in advance which patients will be nonadherent. Preferably, directly observed therapy should be instituted with the help of the local health department.

TREATMENT OF LATENT TUBERCULOSIS INFECTION.

The treatment of children with asymptomatic tuberculosis infection (reactive tuberculin skin test, normal chest radiograph, normal physical examination) to avoid the development of tuberculosis disease is an established practice. The effectiveness of INH therapy in children has approached 100% and has lasted for at least 30 yr. INH therapy should be given to any child with a positive tuberculin skin test but no clinical or radiographic evidence of disease. The currently recommended regimen is 9 mo of daily INH therapy. INH can be given twice weekly under direct observation if adherence with daily treatment is likely to be poor. INH therapy also should be started for children <6 yr of age with a negative tuberculin skin test who have had recent exposure to an adult with infectious tuberculosis, including infants born to mothers who have tuberculosis. These children may already be infected with *M. tuberculosis* but have not yet developed delayed hypersensitivity. Significant tuberculosis disease may develop simultaneously with skin test reactivity in small children and infants, and the illness may develop before the positive skin test is recognized. In exposed children, tuberculin skin testing is repeated 3 mo after contact with the adult source case has been interrupted. If the repeat tuberculin skin test is negative, INH can be discontinued; if the second skin test is reactive (=5?mm), the child has tuberculosis infection and a full course of INH therapy can be administered. Children with HIV infection or other causes of immune suppression should receive 12 mo of treatment.

The optimal treatment for LTBI caused by drug-resistant strains of *M. tuberculosis* has not been established. For infections with strains that are INH resistant only, most experts recommend a 6–9 mo course of RIF. No data from controlled clinical trials support this practice, however. Similarly, no data are available concerning treatment of tuberculosis infection caused by organisms that are resistant to both INH and RIF. Some experts have recommended a combination of a quinolone and PZA for 6–9 mo. An alternative regimen is high-dose EMB and PZA for a similar period of time. For infection with isolates that are resistant to many drugs, the clinician usually administers two drugs to which the organism is susceptible. The efficacy and safety of these regimens in children are not established, and an expert in pediatric tuberculosis should be consulted for treatment of multidrug-resistant tuberculosis infection in children.

Prevention.

The highest priority of any tuberculosis control program should be case finding and treatment, which interrupts transmission of infection between close contacts. All children and adults with symptoms suggestive of tuberculosis disease and those in close contact with an adult suspected of having infectious pulmonary tuberculosis should be tuberculin skin tested and examined as soon as possible. On average, 30–50% of household contacts to infectious cases will be tuberculin skin test positive, and 1% of contacts already have overt disease. This scheme relies on effective and adequate public health response and resources. Children, particularly young infants, should receive high priority during contact investigations because their risk of infection is high and they are more likely to rapidly develop severe forms of tuberculosis.

Mass testing of large groups of children for tuberculosis infection is an inefficient process. When large groups of children at low risk for tuberculosis are tested, the vast majority of skin test reactions are actually false-positive reactions due to biologic variability or cross sensitization with NTM. However, testing of

high-risk groups of adults or children should be encouraged because most of these individuals with positive tuberculin skin tests have tuberculosis infection. Testing should take place only if effective mechanisms are in place to ensure adequate evaluation and treatment of the individuals who test positive.

BACILLE CALMETTE-GUÉRIN VACCINATION.

The only available vaccine against tuberculosis is the BCG, named for the two French investigators responsible for its development. The original vaccine organism was a strain of *M. bovis* attenuated by subculture every 3 wk for 13 yr. This strain was distributed to dozens of laboratories that continued to subculture the organism on different media under various conditions. The result has been production of many BCG vaccines that differ widely in morphology, growth characteristics, sensitizing potency, and animal virulence. The route of administration and dosing schedule for the BCG vaccines are important variables for efficacy. The preferred route of administration is intradermal injection with a syringe and needle because it is the only method that permits accurate measurement of an individual dose. The BCG vaccines are extremely safe in immunocompetent hosts. Local ulceration and regional suppurative adenitis occur in 0.1–1% of vaccine recipients. Local lesions do not suggest underlying host immune defects and do not affect the level of protection afforded by the vaccine. Most reactions are mild and they usually resolve spontaneously, but chemotherapy is needed occasionally. Surgical excision of a suppurative draining node is rarely necessary and should be avoided if possible. Osteitis is a rare complication of BCG vaccination that appears to be related to certain strains of the vaccine that are no longer in wide use. Systemic complaints such as fever, convulsions, loss of appetite, and irritability are extraordinarily rare after BCG vaccination. Profoundly immunocompromised patients may develop disseminated BCG infection after vaccination. Children with HIV infection appear to have rates of local adverse reactions to BCG vaccines that are comparable to rates in immunocompetent children. However, the incidence in these children of disseminated infection months to years after vaccination is currently unknown.

Recommended vaccine schedules vary widely among countries. The official recommendation of the WHO is a single dose administered during infancy, including in asymptomatic HIV-infected children in populations where the risk of tuberculosis is high. In some countries repeat vaccination is universal. In others it is based on either tuberculin skin testing or the absence of a typical scar. The optimal age for administration and dosing schedule are unknown because adequate comparative trials have not been performed.

Although dozens of BCG trials have been reported in various human populations, the most useful data have come from several controlled trials. The results of these studies have been disparate. Some demonstrated a great deal of protection from BCG vaccines, but others showed no efficacy at all. A recent meta-analysis of published BCG vaccination trials suggested that BCG is 50% effective in preventing pulmonary tuberculosis in adults and children. The protective effect for disseminated and meningeal tuberculosis appears to be slightly higher, with BCG preventing 50–80% of cases. A variety of explanations for the varied responses to BCG vaccines have been proposed, including methodologic and statistical variations within the trials, interaction with NTM that either enhances or decreases the protection afforded by BCG, different potencies among the various BCG vaccines, and genetic factors for BCG response within the study populations. BCG vaccination administered during infancy has little effect on the ultimate incidence of tuberculosis in adults, suggesting that the effect of the vaccine is time limited.

In summary, BCG vaccination has worked well in some situations but poorly in others. Clearly, BCG vaccination has had little effect on the ultimate control of tuberculosis throughout the world because more than 5 billion doses have been administered but tuberculosis remains epidemic in most regions. BCG vaccination does not substantially influence the chain of transmission because those cases of contagious pulmonary tuberculosis in adults that can be prevented by BCG vaccination constitute a small fraction of the sources of infection in a population. The best use of BCG vaccination appears to be prevention of life-threatening forms of tuberculosis in infants and young children.

BCG vaccination has never been adopted as part of the strategy for the control of tuberculosis in the United States. Widespread use of the vaccine would render subsequent tuberculin skin testing less useful. However, BCG vaccination may contribute to tuberculosis control in selected population groups. BCG is recommended for tuberculin skin test-negative infants and children who (1) are at high risk of intimate and prolonged exposure to persistently untreated or ineffectively treated adults with infectious pulmonary tuberculosis and cannot be removed from the source of infection or placed on long-term preventive therapy or (2) are continuously exposed to persons with tuberculosis who have bacilli that are resistant to INH and RIF. Any child receiving BCG vaccination should have a documented negative tuberculin skin test before receiving the vaccine. After receiving the vaccine, the child should be separated from the possible sources of infection until it can be demonstrated that the child has had a vaccine response, demonstrated by tuberculin reactivity, which usually develops within 1–3 mo. Occasionally, a second BCG vaccination must be given to children who fail to develop skin test reactivity after the first dose. In the United States, BCG is contraindicated in children with primary or secondary immunodeficiencies.

Active research to develop new tuberculosis vaccines has led to the creation and preliminary testing of several vaccine candidates based on attenuated strains of mycobacteria, subunit proteins, or DNA. The genome of *M. tuberculosis* has been sequenced, allowing researchers to further study and better understand the pathogenesis and host immune responses to tuberculosis.

PERINATAL TUBERCULOSIS.

The most effective way of preventing tuberculosis infection and disease in the neonate or young infant is through appropriate testing and treatment of the mother and other family members. High-risk pregnant women should be tested with a tuberculin skin test, and those with a positive test should receive a chest radiograph with appropriate abdominal shielding. If the mother has a negative chest radiograph and is clinically well, no separation of the infant and mother is needed after delivery. The child needs no special evaluation or treatment if he or she remains asymptomatic. Other household members should receive tuberculin skin testing and further evaluation as indicated.

If the mother has suspected tuberculosis at the time of delivery, the newborn should be separated from the mother until the chest radiograph is obtained. If the mother's chest radiograph is abnormal, separation should be maintained until the mother has been evaluated thoroughly, including examination of the sputum. If the mother's chest radiograph is abnormal but the history, physical examination, sputum examination, and evaluation of the radiograph show no evidence of current active tuberculosis, it is reasonable to assume that the infant is at low risk for infection. The

mother should receive appropriate treatment, and she and her infant should receive careful follow-up care. In addition, all household members should be evaluated for tuberculosis.

If the mother's chest radiograph or acid-fast sputum smear shows evidence of current tuberculosis disease, additional steps are necessary to protect the infant. INH therapy for newborns has been so effective that separation of the mother and infant is no longer considered mandatory. Separation should occur only if the mother is ill enough to require hospitalization, she has been or is expected to become nonadherent with her treatment, or there is strong suspicion that she has drug-resistant tuberculosis. INH treatment for the infant should be continued until the

mother has been shown to be sputum culture negative for at least 3 mo. At that time, a Mantoux tuberculin skin test should be placed on the child. If positive, INH is continued for a total duration of 9–12 mo; if negative, INH can be discontinued. Because INH resistance is increasing in the United States, it is not always clear that INH therapy will be effective for the neonate. If INH resistance is suspected or the mother's adherence to medication is in question, separation of the infant from the mother should be considered. The duration of separation must be at least as long as is necessary to render the mother noninfectious. An expert in tuberculosis should be consulted if the young infant has potential exposure to the mother or another adult with tuberculosis disease caused by an INH-resistant strain of *M. tuberculosis*.

Although INH is not thought to be teratogenic, the treatment of pregnant women with asymptomatic tuberculosis infection is often deferred until after delivery. However, symptomatic pregnant women or those with radiographic evidence of tuberculosis disease should be appropriately evaluated. Because pulmonary tuberculosis is harmful to both the mother and the fetus, and it represents a great danger to the infant after delivery, tuberculosis in pregnant women always should be treated. The most common regimen for drug-susceptible tuberculosis is INH, RIF, and EMB. The aminoglycosides and ETH should be avoided because of their teratogenic effect. The safety of PZA in pregnancy has not been established.

Chapter 198 - Hansen Disease *(Mycobacterium leprae)*

Dwight A. Powell

Hansen disease (leprosy) is a chronic disease resulting from infection with *Mycobacterium leprae* and the ensuing host response. The organs most prominently affected are the respiratory mucosa, skin, and the peripheral nervous system, but testicular and ocular involvement are described. Humans were long believed to be the sole host of *M. leprae*, but naturally acquired infection has been documented in armadillos in the southeastern United States, and experimental infection has been established in primates, nude mice, and armadillos.

Chronic skin lesions, madarosis, sensory neuropathy resulting in the loss of digits or limbs, and paresis secondary to motor nerve dysfunction are among the sequelae of leprosy. The highly visible nature of these debilities led to the historical stigmatization of the “leper.” The psychologic and sociologic sequelae of this stigma can be as debilitating as the disease itself and may result in delays in seeking medical attention. To combat this prejudice, the term **leprosy patient** has replaced the word leper, and **Hansen disease**, after Armauer Hansen who identified *M. leprae* as the cause of leprosy in 1873, has become an accepted designation.

Etiology.

M. leprae, an obligate intracellular pathogen with a generation time of 14 days, is an acid-fast bacillus of the family Mycobacteriaceae. *M. leprae* grows optimally at 27–30°C and cannot be cultured in vitro. The incubation period of leprosy in humans ranges from 3 mo–20 yr (average 3–5 yr). The rare occurrence of leprosy in infants as young as 3 mo of age suggests that in utero transmission may occur or that very short incubation periods may be possible in certain situations.

Epidemiology.

After the introduction of multidrug therapy (MDT) by the World Health Organization (WHO) in 1982, there has been a steady decline in the prevalence of leprosy. On a global scale, the estimated prevalence rate has been reduced 85% from >20 cases/10,000 persons in 1985 to 1.25 cases/10,000 persons in 2000. Approximately 11 million leprosy patients have been cured over the past 15 yr. However, the new

case detection rate has remained nearly steady since 1985 with 750,000 new cases detected and registered for treatment in 2000. The World Health Organization estimates that an additional 2.5 million cases will be detected between the years 2000–2005. The goal by 2005 is to decrease the global prevalence rate to =1 case/10,000 persons. Currently, >90% of the world's leprosy patients reside in 10 major endemic countries in Africa, Southeast Asia, and Central and South America, with 70% residing in India. Approximately 100 cases are reported annually in the United States, of which 85% are in immigrants. Small numbers of endemic cases are reported from Texas, Hawaii, and Louisiana.

Human-to-human transmission accounts for an overwhelming majority of cases; a high percentage of them occur in family members or in close contacts of known patients. Leprosy occurs

at all ages, but infections in infants are extremely rare; incidence rates peak during childhood and early adulthood in endemic areas. HIV infection has not been documented to alter the risk of leprosy in areas of high prevalence for both pathogens.

Pathogenesis.

The entry of *M. leprae* into the human host is poorly understood. Possible modes of transmission include contact with desquamated infected epidermis, ingestion of infected breast milk, and bites of mosquitos or other vectors. At present, however, the basis for most infections appears to be transmission from untreated lepromatous patients by means of prolonged contact with infected nasal secretions containing a high bacterial load. Little is known of the host immune responses in the initial period after infection, but skin testing and serologic studies suggest that up to 80–90% of those infected develop immunity without ever manifesting clinical disease. Studies in endemic areas using polymerase chain reaction (PCR) show widespread presence of the organism in nasal secretions from asymptomatic individuals.

From the nasal mucosa, *M. leprae* appears to be transported hematogenously to skin and peripheral nerves. Using the armadillo model of neuritis, *M. leprae* has been shown to colonize the perineural space and gain access to the interstitium of the endoneural space. Once there, it is available for phagocytosis by Schwann cells surrounding peripheral nerve axons and interstitial macrophages. Intracellular replication of *M. leprae* follows with varying degrees depending on the host cellular immune response. *M. leprae* attachment to and ingestion by Schwann cells has been shown to depend on receptors on the lamin-2 glycoprotein in the basal lamina and the a-dystroglycan complex in the Schwann cell basement membrane. *M. leprae* specific phenolic glycolipid-1 appears to be the ligand mediating this binding. With the recent mapping of the genome of *M. leprae*, more details of this important binding will become available.

Once *M. leprae* has colonized the surface of nerves and has infected endoneural macrophages and Schwann cells, several mechanisms of skin and nerve injury occur depending on the host immune response. One end of the spectrum is **tuberculoid leprosy**, in which there is a vigorous and specific cell-mediated immune response to *M. leprae* antigens. In tissue biopsies there are tightly organized granulomas composed of epithelioid cells and lymphocytes but bacilli are scant or absent. Macrophages, when present, do not contain intracellular organisms. Caseation is rare. Heavy cellular infiltration is found in the dermis with destruction of cutaneous nerve fibers.

At the other end of the spectrum is **lepromatous leprosy**, in which there is total and specific anergy to *M. leprae* both by skin testing and by in vitro assays of cell-mediated immunity. Large amounts of circulating and tissue-based antibody to mycobacterial antigens are present, but they afford no protective immunity. Bacilli are found in enormous numbers in the skin, nasal mucosa, and peripheral nerves. There is continual bacillemia as well as bacillary invasion of all major organs except the central nervous system. Tissue granulomas are poorly formed and are composed chiefly of loose aggregates of foamy histiocytes. Macrophages teeming with undigested bacilli are common. There is extensive, symmetric involvement of peripheral nerves, although the cutaneous nerve endings are usually spared.

An *M. leprae*–specific suppressor T-cell population is found in the circulation of patients with lepromatous leprosy, and increased numbers of suppressor T cells are found in their skin granulomas. T cells from lepromatous patients also produce less interleukin 2 and less interferon-? after stimulation with *M. leprae* antigens than do T cells from tuberculoid patients or normal controls.

Borderline or dimorphous leprosy is subdivided into three subclasses that lie between the tuberculoid and lepromatous poles.

Clinical Manifestations

INDETERMINATE LEPROSY (IL).

Indeterminate leprosy is the earliest clinically detectable form of leprosy. Although it is observed in only 10–20% of infected individuals, it is a stage through which most patients with advanced leprosy have passed. Usually there is a single hypopigmented macule, 2–4?cm in diameter, with a poorly defined border but having no erythema or induration. Anesthesia is minimal or absent, particularly if the lesion is on the face. Tissue samples may contain granulomas, but bacilli are rarely demonstrable. The histopathology is not distinctive; the diagnosis is usually made by exclusion of other skin disorders in contacts (especially children) of leprosy patients. In 50–75% of patients with indeterminate leprosy, the lesions heal spontaneously; in the remainder, they progress to one of the classic forms.

TUBERCULOID LEPROSY (TL).

There is usually a single, large (often >10?cm in diameter) lesion with a well-demarcated, elevated erythematous rim. The interior of the lesion is flat, atrophic, hypopigmented, occasionally scaly, and anesthetic. Rarely, there may be as many as four lesions. The closest superficial nerve is often impressively thickened. The ulnar, posterior tibial, and great auricular nerves are most commonly affected. Periodic examination of all leprosy patients and their contacts should include palpation of these nerves. Without therapy, the skin lesion tends to enlarge

slowly, but documented instances of spontaneous resolution exist. The coloration of the rim slowly fades with therapy and the induration resolves, resulting in a flat lesion with central hypopigmentation and a ring of postinflammatory hyperpigmentation. Loss of hair follicles, sweat glands, cutaneous nerve receptors, and sensation in the central portion of the lesion is irreversible. Marked improvement should be apparent within 1–2 mo after initiating therapy, but complete resolution may take up to 8–12 mo. There is an entity of "pure neural" tuberculoid leprosy, which presents as either pure sensory or combined sensory and motor nerve dysfunction with prominent nerve thickening but no cutaneous lesions. Histopathology is mandatory to establish this diagnosis. Nerve trunk size varies widely, and over diagnosis of "enlarged" nerves is common among inexperienced observers. Nodular or fusiform nerve thickening has greater diagnostic value than a palpable nerve that is smooth and symmetric.

BORDERLINE LEPROSY.

The clinical and histologic criteria for the three subdivisions of borderline leprosy are less well defined than are those of the two polar categories. In contrast to the tuberculoid and lepromatous patterns, those in the borderline divisions are unstable. For example, host or bacterial factors can result in immunologic downgrading of the clinical condition toward the lepromatous pattern or upgrading it toward the tuberculoid pattern. Therapy is the most common cause of upgrading reactions; downgrading can be seen in conditions that compromise host immunity, for example, pregnancy. Clinical characteristics of the three generally accepted borderline subclasses are as follows.

In the **borderline tuberculoid (BT)** pattern, the lesions are greater in number but smaller in size than in tuberculoid leprosy. There may be small satellite lesions around older lesions, and the margins of the borderline tuberculoid lesions are less distinct. There is usually thickening of two or more superficial nerves.

In the **borderline (BB)** pattern, the lesions are more numerous and more heterogeneous in appearance. They may become confluent, and plaques may be present. The borders are poorly defined, and the erythematous rim fades into the surrounding skin. There may be anesthesia, but hypesthesia is more common. Mild to moderate nerve thickening is common, but severe muscle wasting and neuropathy are unusual.

In the **borderline lepromatous (BL)** pattern, a large number of asymmetrically distributed lesions are heterogeneous in appearance. Macules, papules, plaques, and nodules may all

coexist. Individual lesions are small unless confluent. Anesthesia is mild and superficial nerve trunks are spared. The initial response to therapy is often dramatic; nodules and plaques flatten within 2–3 mo. With continued therapy, the lesions become macular and almost invisible.

LEPROMATOUS LEPROSY (LL).

The lesions are innumerable, often confluent, and symmetric. Initially there may be only vague macules or even uniform, diffuse skin infiltrations without discernible lesions. As the disease progresses, the lesions become increasingly papular and nodular, so that with the diffuse thickening and infiltration of the skin, the characteristic leonine facies accompanied by loss of the eyebrows and distortion of the earlobes becomes apparent. Anesthesia of the lesions is less severe than in tuberculoid leprosy, but a symmetric peripheral sensory neuropathy usually develops late in the course of the disease. Testicular infiltration leading to azoospermia, infertility, and gynecomastia is common in adults but not in children. Bacilli are demonstrable in most internal organs other than the central nervous system, but tissue damage or interference with function is infrequent. Glomerulonephritis, when it occurs, is believed to be secondary to immune complex deposition rather than to infection per se. The initial response to therapy may be encouraging but is often followed by a long (2–5 yr) period of very slow improvement. In true lepromatous leprosy, the specific anergy to the leprosy bacillus persists despite therapy, thus making the patient theoretically susceptible to relapse if even a single viable bacillus remains at the end of therapy.

REACTIONAL STATES.

Acute clinical exacerbations are common in leprosy and are believed to reflect abrupt changes in the host-parasite immunologic balance. Although these reactional states do occur in the absence of therapy, they are especially common during the initial years of treatment. Approximately 30% of patients receiving effective chemotherapy can develop reactions, and, unless adequately treated, they will result in crippling deformities. Two major variants are recognized.

Type 1 (reversal) reactions are observed predominantly in borderline leprosy and result from a sudden increase in effective cell-mediated immunity in response to *M. leprae* antigens in dermis and Schwann cells. Acute tenderness and swelling at the site of existing cutaneous and neural lesions and the development of new lesions are the major manifestations. Existing or new skin lesions often ulcerate to leave hideous scars. Fever and systemic toxicity are uncommon, but the acute neuritis that can present either as a severe painful episode or be insidious and painless can lead to irreversible nerve injury (anesthesia, facial paralysis, claw hand, footdrop) if not treated immediately. Reversal reactions constitute perhaps the only medical emergency related to leprosy per se. Patients should be instructed to contact their physicians immediately if signs of a reaction appear.

Type 2 (erythema nodosum leprosum) reactions (ENL) occur in lepromatous and borderline lepromatous cases as a systemic inflammatory response to deposition of extravascular immune complexes of antibody and *M. leprae* antigen. Tender red dermal papules or nodules, clinically resembling erythema nodosum, are the hallmarks of this syndrome. They develop in a few hours and last only a few days. High fever, migrating polyarthralgia, painful swelling of lymph nodes or spleen, orchitis, iridocyclitis, and, rarely, nephritis may occur. Leukocytosis and albuminuria may be present. Circulating and tissue-based immune complexes are frequently present and may explain the resemblance to other immune complex disorders, but

the underlying mechanism appears to involve the activation of a helper T-cell subset. There is a strong tendency to recurrence (45% of patients), and there is a risk of amyloidosis and renal failure if treatment is inadequate.

Diagnosis.

The critical factor in the diagnosis of leprosy is its inclusion in the differential diagnosis of a skin disorder in anyone who has resided in an endemic leprosy region. Anesthetic skin lesions with or without thickened peripheral nerves are virtually pathognomonic of leprosy. A full-thickness skin biopsy from an active lesion (stained with both a standard histologic stain and an acid-fast stain such as Fite-Faraco) is the optimal procedure for confirmation of the diagnosis and accurate disease classification. Acid-fast bacilli are rarely found in patients with indeterminate or tuberculoid disease, but the presence of granulomas and lymphocytic infiltration of nerves in anesthetic skin lesions essentially confirms the diagnosis. For purposes of assigning patients to the appropriate WHO MDT regimen, slit skin smears are assessed to determine whether patients have paucibacillary infection (=5 skin lesions and no bacilli on skin smears) or multibacillary infection (=6 skin lesions and bacilli on skin smears). The bacterial index can range from zero (no bacilli in 100 oil-immersion fields) to 6+ (>1,000 bacilli per field). Other routine clinical, microbiologic, and radiologic tests have little or no role in the diagnosis of leprosy, although they may be useful in the exclusion of other diagnoses. Various assays for serum antibodies directed against unique antigens of *M. leprae* have been developed, but current tests lack sufficient sensitivity and specificity for active disease to be useful for clinical diagnostic purposes. PCR analysis has been found to detect *M. leprae* only when biopsy specimens are positive for acid-fast bacilli.

DIFFERENTIAL DIAGNOSIS.

Many diseases endemic in developing countries can mimic the appearance of leprosy; these include secondary syphilis, cutaneous leishmaniasis, yaws, and cutaneous fungal infections. None of these entities involve paresthesia/anesthesia localized to the skin lesions or cause thickening of peripheral nerves. The presence of nerve thickening with skin lesions also differentiates leprosy from primary neurologic disease. Indeterminate leprosy may present as minimal anesthesia, no nerve thickening, and equivocal histopathology, suggesting a superficial fungal infection, particularly tinea versicolor. The diagnosis of indeterminate leprosy should be considered one of exclusion and will rarely be established in anyone other than a close contact of a known lepromatous patient.

Treatment.

Physicians in the United States considering the diagnosis or treatment of leprosy are strongly encouraged to obtain consultation and assistance in patient management from the National Hansen Disease Programs (800-642-2477; *http://bphc.hrsa.gov/nhdp/default.htm*).

Only three antimycobacterial agents have proven to be consistently effective in the treatment of leprosy. Since the early 1940s, dapsone has remained the cornerstone of therapy because of its low cost, minimal toxicity, and wide availability. However, secondary resistance develops when it is used as the sole agent. Dermatitis, hepatitis, and methemoglobinemia are the most common side effects; granulocytopenia is rare but potentially fatal. Dose-related hemolytic anemia, which can be severe, is seen in patients with glucose-6-phosphate dehydrogenase deficiency, methemoglobin reductase deficiency, or hemoglobin M. Pregnancy studies have not shown an increased risk of fetal abnormalities.

Rifampin is the most rapidly mycobactericidal drug for *M. leprae*, achieving excellent levels inside cells, where most leprosy bacilli reside. Resistance develops when Rifampin is used as the sole agent. The widespread use of rifampin has been limited by cost more than by toxicity. Hepatitis is the most common side effect that necessitates discontinuance.

Clofazimine, a phenazine dye with both antimycobacterial and anti-inflammatory activity, has been particularly useful in decreasing the incidence of reactional states. The pharmacokinetics are poorly understood, but the half-life is several days. The drug is avidly taken up by epithelial cells, a feature that may be important for its activity but also results in cutaneous hyperpigmentation, ichthyosis, xerosis, and enteritis. The intense reddish-brown

discoloration of the skin is cosmetically a deterrent to use and often results in discontinuation or poor compliance.

Minocycline, certain second-generation quinolones, and some new macrolide derivatives such as clarithromycin have shown promise in experimental models but limited human treatment data exist.

Introduced by the WHO in 1982, multidrug therapy has been very successful with a high cure rate and a relapse rate of 1%/yr following a full course of therapy. For adults with multibacillary leprosy (all BL and lepromatous patients), therapy is recommended for 12–24 mo to include rifampin (600?mg once monthly PO, directly observed), dapsone (100?mg once daily PO, self-administered), and clofazimine (300?mg once monthly, directly observed, and 50?mg once daily PO, self-administered). For adults with paucibacillary leprosy (all indeterminate, TT, and most BT patients), therapy is recommended for 6 mo with rifampin (600?mg once monthly PO, directly observed) and dapsone (100?mg once daily PO, self-administered). Patients who experience relapse are re-treated with the same regimens. To date there have been no patients treated with WHO recommended MDT who have experienced secondary Rifampin resistance in contrast to those treated with Rifampin monotherapy or multidrug therapy not recommended by WHO. Resistance is difficult to determine at present, requiring an in vivo mouse footpad test of 12 mo duration. Newer genetic testing models evaluating for resistance-associated mutations in the *rpoB* gene of *M. leprae* are much faster and appear very accurate.

Patients treated in the United States may be advised to receive regimens that vary from WHO recommendations. Adults with paucibacillary disease receive dapsone (100?mg once daily PO) and rifampin (600?mg once daily PO)for 12 mo; those with multibacillary disease receive dapsone (100?mg once daily PO), rifampin (600?mg

once daily PO), and clofazimine (50?mg once daily PO) for 24 mo. Daily pediatric doses are dapsone 1?mg/ kg, rifampin 10?mg/kg, and clofazimine 1?mg/kg, not to exceed the recommended adult doses.

Therapy for reactional states can be complicated and generally requires expert consultation. Management depends on maintenance of antimycobacterial drugs, effective and prolonged anti-inflammatory therapy, and adequate analgesia and physical support during the phase of active neuritis. Mild ENL may respond to nonsteroidal anti-inflammatory agents. More severe ENL usually requires corticosteroid therapy (prednisolone 1?mg/kg/24?hr) but often relapses when the drug is discontinued. Clinical remission of acute or suppression of chronic ENL can be achieved with thalidomide. A dose of 100?mg qid will usually control the reaction within 48?hrs. The dose is then tapered to a maintenance level of around 100?mg/24?hr, and every few months an attempt should be made to wean patients off the drug altogether. *Thalidomide is absolutely contraindicated in women of child-bearing age*; otherwise it is much safer than corticosteroids for chronic use. The major side effect is fatigue. Pediatric dosages have not been established. Clofazimine 300?mg/24?hr tapering to 100?mg/24?hr or less for 12 mo is also useful in managing chronic ENL. Type 1 reversal reactions are optimally treated with high-dose corticosteroids (prednisolone 20–40?mg/ 24?hr PO in adults, and 1?mg/kg/24?hr PO in children) tapered over several months. Alternate-day regimens may be effective in patients with frequent relapses requiring prolonged treatment.

Prognosis.

The prognosis for arresting progression of tissue and nerve damage is good, but recovery of lost sensory and motor function is variable and generally incomplete; hyperpigmentation, hypopigmentation, and loss of hair follicles or sweat glands persist. Intercurrent reactional states, poor compliance, and emergence of drug resistance can all lead to clinical exacerbations or relapses necessitating close follow-up of patients. Much of the chronic debility results from repeated trauma to anesthetic digits and limbs. Careful counseling of patients and consultation with physical and occupational therapy services is essential for an optimal outcome.

Prevention.

Two approaches are advocated for interrupting leprosy transmission in endemic areas. The first is directed at the risk of infection among household contacts of leprosy patients, especially those with multibacillary disease. It is based on regular periodic examination of contacts and early treatment at the first evidence of leprosy. The second is the use of bacille Calmette-Guerin (BCG) vaccination. One dose of BCG appears to be 50% protective against leprosy; a second dose increases the protective benefit.

One historical practice that has fortunately been abandoned is the forcing of leprosy patients into a leprosarium. Mouse footpad inoculation studies have demonstrated that viability of *M. leprae* in skin biopsies decreases sharply within 3 wk of initiating therapy with dapsone and rifampin. This rapid decrease in infectivity combined with the high probability that family members have already had prolonged exposure to the patient before the diagnosis makes physical isolation of leprosy patients unnecessary.

Chapter 199 - Nontuberculous Mycobacteria

Dwight A. Powell

Nonleprous, nontuberculous *Mycobacterium* (NTM), which are also referred to as **atypical mycobacteria, mycobacteria other than tuberculosis (MOTT)**, or potentially pathogenic environmental mycobacteria, are members of the family of Mycobacteriaceae. They differ from *M. tuberculosis* in their nutritional requirements, ability to produce pigments, enzymatic activity, and susceptibility patterns to antituberculous drugs. In contrast to *M. tuberculosis*, NTM are generally acquired from contact with the environment rather than by person-to-person spread.

Etiology.

Fourteen strains of NTM are associated with human infections. Phenotypically, they are divided into four groups described by Runyon in 1959 (Table 199–1) based on their colony growth and morphology on solid media. Groups I, II, and III are slow growing (>7 days to detect growth); group IV is rapid growing (<7 days to detect growth). Photochromogens form pigment after exposure to light, scotochromogens form pigment in the dark, and nonchromogens fail to produce pigment. Species and serovars of NTM are now defined by biochemical reactions, antibody specificity, radiolabeled DNA probes, DNA restriction fragment length polymorphism, or ribosomal-RNA sequencing. Biochemically and immunologically related species

TABLE 199-1 -- **Classification of Nontuberculous Mycobacteria Associated with Human Disease**

Runyon Group	Mycobacteria
I. Photochromogens	*M. kansasii* *M. marinum* *M. simiae*
II. Scotochromogens	*M. scrofulaceum* *M. xenopi* *M. szulgai*
III. Nonchromogens	*M. avium* *M. intracellulare* *M. malmoense* *M. haemophilum* *M. ulcerans*
IV. Rapid growers	*M. chelonae* *M. fortuitum* *M. abscessus*

that are difficult for clinical laboratories to differentiate are often referred to as “complexes,” such as the ***M. fortuitum* complex** *(M. fortuitum* and *M. chelonae)* and the ***M. avium* complex** *(M. avium* and *M. intracellulare)*.

Epidemiology.

NTM are distributed worldwide and are ubiquitous in the environment, existing as saprophytes in soil and water; as pathogens in swine, birds, and cattle; and as part of the normal human pharyngeal flora. Some NTM have well-defined ecologic niches that help explain transmission patterns. The natural reservoir for *M. marinum* is fish and other cold-blooded animals, so infections follow injury in an aquatic environment. *M. fortuitum* and *M. chelonae* are ubiquitous in the hospital environment and have caused clusters of nosocomial surgical wound and venous catheter-related infections. *M. ulcerans* is recovered only from soils and waters of rain forests and is associated with chronic skin infections in the tropics. *M. avium* complex is found in abundance in the waters, soils, and aerosols of the acid, brown-water swamps of the southeastern United States. In rural counties in this region, asymptomatic infections with *M. avium* complex approach 70% by adulthood.

With the exception of cervical lymphadenitis, illness related to NTM infections is relatively uncommon in children. Infection with NTM, particularly *M. avium* complex, is one of the most common terminal infections in patients with AIDS.

Pathogenesis.

The histologic appearances of lesions produced by *M. tuberculosis* and NTM are often indistinguishable. The classic pathologic lesion consists of caseating granulomas. However, compared with *M. tuberculosis*, NTM infections are more likely to result in granulomas that are noncaseating, ill-defined (nonpalisading), and irregular or serpiginous. Granulomas may be absent, with only chronic inflammatory changes observed. In patients with AIDS and disseminated NTM infection, the inflammatory reaction is usually scant and tissues are filled with large numbers of histiocytes packed with acid-fast bacilli.

Clinical Manifestations.

Lymphadenitis of the superior anterior cervical or submandibular nodes is the most

frequent manifestation of NTM infection in children. Preauricular, posterior cervical, axillary, and inguinal nodes are involved occasionally. Lymphadenitis is most common in children 1–5 yr of age because of their tendency to put objects contaminated with soil, dust, or standing water into their mouths. Affected children usually lack constitutional symptoms and present with a unilateral subacute and slowly enlarging lymph node or group of closely approximated nodes >1.5?cm that are firm, painless, freely movable, and not erythematous (Fig. 199–1). The involved nodes occasionally resolve without treatment, but most undergo rapid suppuration after several weeks. The center of the node becomes fluctuant, and the overlying skin becomes erythematous and thin. Eventually, the

Figure 199-1 An enlarging cervical lymph node with nontuberculous mycobacterial infection, which is firm, painless, freely movable, and not erythematous.

nodes rupture and form cutaneous sinus tracts that drain for months or years, resembling the classic scrofula of tuberculosis (Fig. 199–2). In the United States, *M. avium* complex accounts for approximately 80% of NTM lymphadenitis in children. *M. scrofulaceum* and *M. kansasii* account for most other cases, particularly in the southwestern United States. Rarely, *M. xenopi, M. malmoense, M. haemophilum*, and *M. szulgai* are described.

Cutaneous disease due to NTM is rare in children. Infection usually follows percutaneous inoculation with fresh or salt water contaminated by *M. marinum*. Within several weeks of exposure, a solitary nodule develops at the site of minor abrasions on the elbows, knees, or feet (**swimming pool granuloma**) and on the hands and fingers of fish fanciers (**fish tank granuloma**). The lesions are usually nontender and enlarge over 3–5 wk to ulcerated granulomas or warty lesions, as seen in cutaneous tuberculosis. The lesions sometimes resemble sporotrichosis; satellite lesions near the site of entry extend along the skin following the superficial lymphatics. Lymphadenopathy is usually absent. Although most infections remain localized to skin, penetrating *M. marinum* infections may result in tenosynovitis, bursitis, osteomyelitis, or arthritis.

M. ulcerans also causes cutaneous infection in children living in tropical countries (Africa, Australia, Asia, and South America). Infection follows percutaneous inoculation and presents as a painless erythematous nodule, most frequently on a leg, which

Figure 199-2 A ruptured cervical lymph node with nontuberculous mycobacterial infection, which resembles the classic scrofula of tuberculosis.

undergoes central necrosis and ulceration. The lesion, often called a **Buruli ulcer** after the region in Uganda where most cases are reported, has a characteristic undermined edge, gradually expands, and may result in extensive soft tissue destruction with secondary bacterial infection. The lesion may heal slowly over 6–9 mo or may continue to spread, leading to deformities and contractures.

Skin and soft tissue infections due to *M. fortuitum*, *M. chelonae*, or *M. abscessus* are rare in children and usually follow percutaneous inoculation due to puncture wounds and minor abrasions. Clinical disease usually arises after a 4–6 wk incubation period and presents as a localized cellulitis, painful nodules, or a draining abscess. A unique case has been described of mastitis due to *M. abscessus* following insertion of a nipple ring. *M. haemophilum* may cause painful subcutaneous nodules, which often ulcerate and suppurate in immunocompromised patients, particularly after renal transplant.

Nontuberculous mycobacteria are uncommon sources of catheter-associated infections, but are becoming increasingly recognized. These are most commonly caused by *M. fortuitum, M. chelonae*, or *M. abscessus* and may present as bacteremia or localized catheter tunnel infections.

Pulmonary infections, although the most common cause of NTM illness in adults, are uncommon in children. *M. avium* complex has been described as a cause of acute pneumonitis, chronic cough, or wheezing associated with paratracheal or peribronchial lymphadenitis and airway compression in normal children. Rare cases of progression to endobronchial granulation tissue have been reported. Chronic infections in older cystic fibrosis patients have been caused by *M. avium* complex and *M. fortuitum* complex. *M. kansasii, M. xenopi*, and *M. szulgai* are uncommon in children and usually occur in adults with underlying chronic lung disease. The onset is insidious and consists of low-grade fever, cough, night sweats, and generalized malaise. Thin-walled cavities with minimal surrounding parenchymal infiltrates are characteristic, but radiographic findings may resemble those of tuberculosis.

In unusual circumstances, NTM cause bone and joint infections that are indistinguishable from those produced by *M. tuberculosis* or bacterial agents. Such infections usually result from operative incision or accidental puncture wounds. *M. fortuitum* infections from puncture wounds of the foot resemble infections caused by *Pseudomonas aeruginosa* and *Staphylococcus aureus*.

Disseminated disease, usually associated with *M. avium* complex infections, occurs occasionally in children without any apparent immunodeficiency. Most of these patients have mutations in genes coding for the interferon-? receptor (IFNGR) or the interleukin-12 (IL-12) receptor, or for IL-12 production. Those patients with complete IFNGR deficiency have severe disease that is difficult to treat. Those with partial IFNGR deficiency or IL-12 pathway mutations have milder disease that may respond to interferon and antimycobacterial therapy. Multifocal osteomyelitis is particularly prevalent in individuals with the IFNGR1 818del4 mutation. Recurrence, years after a course of treatment, has been well documented.

Disseminated disease due to *M. avium* complex infections is among the most common opportunistic infections in patients with AIDS, usually late in the illness when CD4 cell counts are <100 cells/mm^3 . Colonization of the respiratory or gastrointestinal tract probably precedes disseminated *M. avium* complex infections, but screening studies of respiratory secretions or stool samples are not useful to predict dissemination. Continuous high-grade bacteremia is usual, and multiple organs are infected, including most commonly lymph nodes, liver, spleen, bone marrow, and gastrointestinal tract. Thyroid, pancreas, adrenal gland, kidney, muscle, and brain may be involved. The most common signs and symptoms of disseminated

M. avium complex infections in AIDS patients are fever, night sweats, chills, anorexia, marked weight loss, wasting, weakness, generalized lymphadenopathy, and hepatosplenomegaly. Jaundice, elevated alkaline phosphatase level, anemia, and neutropenia may occur. Imaging studies usually demonstrate massive lymphadenopathy of hilar, mediastinal, mesenteric, or retroperitoneal nodes. In children with AIDS, the mean survival time after isolation of *M. avium* complex from a body source is 5–9 mo.

Diagnosis.

The differential diagnosis of NTM lymphadenitis includes acute bacterial lymphadenitis, tuberculosis, cat-scratch disease (*Bartonella henselae*), mononucleosis, toxoplasmosis, brucellosis, tularemia, and malignancies, especially lymphomas. An intermediate strength tuberculin skin test (5 tuberculin units) is usually weakly positive with 5–15?mm induration. Although the Centers for Disease Control and Prevention have produced skin tests representing the different Runyon groups of NTM, these antigens are no longer available. Differentiation between NTM and *M. tuberculosis* may be difficult, but children with NTM lymphadenitis usually have a Mantoux tuberculin skin test reaction <15?mm in duration, unilateral anterior cervical node involvement, a normal lung roentgenogram, and no exposure to adult tuberculosis; children with tuberculous lymphadenitis more often have bilateral posterior cervical node involvement, a Mantoux tuberculin skin test reaction =15?mm in duration, an abnormal lung roentgenogram, or exposure to adult tuberculosis. Definitive diagnosis requires excision of involved nodes and recovery of the responsible pathogen.

Diagnosis of cutaneous infections depends on isolating the responsible microorganisms from an excised lesion. The diagnosis of pulmonary NTM infection in children is difficult because many species of NTM, including *M. avium* complex, can be isolated from oral and gastric secretions of healthy children. Definitive diagnosis requires invasive procedures such as bronchoscopy and pulmonary or endobronchial biopsy. Mycolic acids and other lipids in the cell wall of mycobacteria give them their hallmark trait of acid-fastness with the Ziehl-Neelsen or Kinyoun stains. They may also be identified with the fluorochrome stain auramine-rhodamine. The sensitivity of these stains for detecting NTM in tissue samples is less than with *M. tuberculosis*.

Blood cultures are 90–95% sensitive in AIDS patients with disseminated infection. *M. avium* complex may be detected within 7 days of inoculation in nearly all patients with the BACTEC radiometric blood culture system. Commercially available DNA probes differentiate NTM from *M. tuberculosis*. Identification of histiocytes containing numerous acid-fast bacilli from bone marrow and other biopsy tissues provides a rapid presumptive diagnosis of disseminated mycobacterial infection.

Treatment.

Therapy for NTM infections involves medical, surgical, or combined treatment. Isolation of the infecting strain followed by susceptibility testing is ideal because susceptibility patterns vary. *M. kansasii, M. marinum, M. xenopi, M. ulcerans*, and *M. malmoense* are usually susceptible to some standard antituberculous drugs. *M. fortuitum, M. chelonae, M. scrofulaceum*, and *M. avium* complex are often resistant to standard antituberculous drugs but have variable susceptibility to newer antibiotics such as quinolones and macrolides. Multiple drug therapy is essential to avoid development of resistance.

The preferred treatment of NTM lymphadenitis is complete surgical excision. Nodes should be removed while still firm and encapsulated. Excision is more difficult if extensive caseation with extension to surrounding tissue has occurred, and complications of facial nerve damage or recurrent infection are more likely. Incomplete surgical excision is not advised because chronic drainage may develop. Standard antituberculous medications have little effect on NTM lymphadenitis and are not necessary with complete excision. If there is concern for *M. tuberculosis* infection, therapy with isoniazid, rifampin, and pyrazinamide should be given until cultures confirm the cause. If for some reason surgery of NTM lymphadenitis cannot be performed,

removal of infected tissue is incomplete, or recurrence or chronic drainage develops, a 4–6 mo trial of chemotherapy is warranted. Although there are no published controlled trials, several case reports and small series have reported successful treatment with chemotherapy alone or combined with surgical excision. Clarithromycin or azithromycin combined with rifabutin or ethambutol are the most commonly reported therapy regimens.

Cutaneous NTM lesions usually heal spontaneously after incision and drainage without other therapy. *M. marinum* is susceptible to rifampin, amikacin, ethambutol, sulfonamides, trimethoprim-sulfamethoxazole, and tetracycline. Therapy with a combination of these drugs may be given for 3–4 mo. Corticosteroid injections should not be used. Superficial infections with *M. fortuitum* or *M. chelonae* usually resolve after surgical incision and open drainage, but deep-seated or catheter-related infections require removal of infected central lines and therapy with parenteral amikacin plus cefoxitin or clarithromycin. Pulmonary infections should be treated initially with isoniazid, rifampin, and pyrazinamide pending culture identification and susceptibility testing.

Patients with disseminated *M. avium* complex and IL-12 pathway defects or deficiency of IFNGR should be treated for at least 12 months with clarithromycin or azithromycin combined with one or more second-line drugs (rifabutin, clofazimine, ethambutol, or a quinolone). In vitro susceptibility testing is important. Once the clinical illness has resolved, lifelong daily prophylaxis with clarithromycin is advisable to prevent recurrent disease. The use of interferon adjunctive therapy is determined by the specific genetic defect.

In adults with AIDS, daily prophylaxis with azithromycin with or without rifabutin reduces infection with *M. avium* complex by >50%. Although pediatric studies are lacking, the U.S. Public Health Service recommends either azithromycin (20?mg/kg once weekly PO; maximum: 1200?mg/dose) or clarithromycin (7.5?mg/kg/dose bid PO; maximum: 500?mg/dose) for HIV-infected children with the following indications: for children =6 yr, CD4 count <50/µL; 2–6 yr, CD4 count <75/µL; 1–2 yr, CD4 count <500/µL; <1 yr, CD4 count <750?µL.

Section 6 - *Spirochetal Infections*

Chapter 200 - Syphilis (*Treponema pallidum*)

Parvin Azimi

Etiology.

Syphilis is a systemic communicable infection caused by *Treponema pallidum*, a long, slender, tightly coiled, motile spirochete with finely tapered ends belonging to the family Spirochaetaceae. The pathogenic members of this genus include *T. pallidum* (venereal syphilis), *T. pertenue* (yaws), *T. pallidum* subsp. *endemicum* (endemic syphilis), and *T. carateum* (pinta). Because these microorganisms stain poorly, detection in clinical specimens requires dark-field microscopy or direct immunofluorescent staining techniques. *T. pallidum* cannot be cultured in vitro but has been propagated by intratesticular inoculation in rabbits.

Epidemiology.

Two forms of syphilis are encountered in children. Acquired syphilis is transmitted almost exclusively by sexual contact. Less frequent modes of transmission include transfusion of contaminated blood or direct contact with infected tissues. After an epidemic resurgence of primary and secondary syphilis in the 1980s in the United States that peaked in 1989, the annual rate has declined and in 1997 was the lowest since reporting for syphilis began in 1941. Rates further declined in 2000 due to targeted United States public health efforts in the racial/ethnic minority population at risk. Despite these declines, syphilis remains endemic in parts of the south, where it is more common (3.8 per 100,000 population) than in the midwest (2.0), northeast (0.7), and west (1.0). The rates for primary and secondary syphilis remain substantially higher for blacks (12.8 per 100,000 population) than for nonwhite Hispanics (1.8) and for non-Hispanic whites (0.6).

Congenital syphilis results from transplacental transmission of spirochetes. Pregnant women with primary and secondary syphilis and spirochetemia are more

likely to transmit infection to the fetus than are women with latent infection. Transmission can occur at any stage of pregnancy. The incidence of congenital infection in the offspring of untreated infected women remains highest during the first 4 yr after acquisition of primary infection, secondary, and early latent disease. The risk factors most commonly associated with congenital syphilis are lack of prenatal care and cocaine drug abuse, which is associated with prostitution, unprotected sexual contact, and trading of sex for drugs, in addition to inadequate prenatal care of pregnant addicts.

Clinical Manifestations.

Primary syphilis is characterized by syphilitic chancre and regional lymphadenitis. A painless papule appears at the site of inoculation 2–6 wk after *T. pallidum* has been introduced. The papule soon develops into a clean, painless ulcer with raised borders called a chancre. The chancre, usually on the genitals, contains viable *T. pallidum* and is highly

contagious. Extragenital chancres can also be seen, depending on the site of primary inoculation. Adjacent lymph nodes are generally enlarged. The chancre heals spontaneously within 4–6 wk, leaving a thin scar.

Untreated patients develop manifestations of **secondary syphilis** 2–10 wk after the chancre heals. Manifestations of secondary syphilis are related to spirochetemia and include a nonpruritic maculopapular rash, which can cover the entire body, involving palms and soles; pustular lesions may also develop. **Condylomata lata** (gray-white to erythematous wartlike plaques) can occur in moist areas around the anus and vagina, and white plaques called mucous patches may be found in mucous membranes. A flulike illness with low-grade fever, headache, malaise, anorexia, weight loss, sore throat, myalgias, and arthralgias, and generalized lymphadenopathy is often present. Renal, hepatic, and ophthalmologic manifestations may be present, as may be meningitis, which occurs in 30% of patients with secondary syphilis, manifested by cerebrospinal fluid (CSF) pleocytosis and elevated protein level, although the patient may not show neurologic symptoms. Secondary infection becomes **latent** within 1–2 mo after the onset of the rash. Relapses with secondary manifestations can be seen during the 1st year of latency. This period is referred to as the **early latent period**. No relapses occur after the 1st year; what follows is late syphilis, which may be either asymptomatic (**late latent**) or symptomatic (**tertiary**). At this stage, patients may begin showing the manifestations of tertiary disease, which include neurologic, cardiovascular, and gummatous lesions. The latter are granulomas of the skin and musculoskeletal system resulting from the host's delayed hypersensitivity reaction.

CONGENITAL INFECTION.

Syphilis during pregnancy has a transmission rate approaching 100%. Fetal or perinatal death occurs in 40% of affected infants. Among survivors, manifestations have traditionally been divided into early and late stages. **Early signs** appear during the first 2 yr of life, whereas **late signs** appear gradually during the first 2 decades. Early manifestations result from transplacental spirochetemia and are analogous to the secondary stage of acquired syphilis. Approximately two thirds of infected infants are asymptomatic at the time of birth and are identified only by routine prenatal screening; if they are untreated, symptoms develop within weeks or months.

The early manifestations of congenital infection are varied and involve multiple organ systems. Hepatosplenomegaly, jaundice, and elevated liver enzymes are common. Histologically, liver involvement includes bile stasis, fibrosis, and extramedullary hematopoiesis. Lymphadenopathy tends to be diffuse and resolve spontaneously; shotty nodes may persist. Coombs negative hemolytic anemia is characteristic. Thrombocytopenia is often associated with platelet trapping in an enlarged spleen. Characteristic osteochondritis and periostitis (Fig. 200–1) and mucocutaneous rash (Fig. 200–2), presenting with erythematous maculopapular or bullous lesions, followed by desquamation involving hands and feet, are common. Mucous patches, rhinitis (**snuffles**), and condylomatous lesions are highly characteristic features of mucous membrane involvement in congenital syphilis. Bone involvement occurs frequently. Roentgenographic abnormalities include multiple sites of osteochondritis at the wrists, elbows, ankles, and knees; and periostitis of the long bones, and rarely the skull. The osteochondritis is painful and often results in irritability and refusal to move the involved extremity (**pseudoparalysis of Parrot**). Central nervous system (CNS) abnormalities, failure to thrive, chorioretinitis, nephritis, and nephrotic syndrome may also be seen. Clinical manifestations of renal involvement include hypertension, hematuria, proteinuria, hypoproteinemia, hypercholesterolemia, and hypocomplementemia. They appear to be related to glomerular deposition of circulating immune complexes. Less common clinical manifestations of early congenital syphilis include gastroenteritis,

Figure 200-1 Osteochondritis and periostitis in a newborn with congenital syphilis.

peritonitis, pancreatitis, pneumonia, eye involvement (glaucoma and chorioretinitis), nonimmune hydrops, and testicular masses.

The late manifestations result primarily from chronic inflammation of bone, teeth, and the CNS. Skeletal changes due to persistent or recurrent periostitis and associated thickening of bone include frontal bossing, a bony prominence of the forehead (“**olympian brow**”); unilateral or bilateral thickening of the sternoclavicular portion of the clavicle (**Higouménakis sign**); an anterior bowing of the midportion of the tibia (**saber shins**); and scaphoid scapula, a convexity along its medial border. Dental abnormalities are common and include (1) **Hutchinson teeth** (Fig. 200–3), which are the peg or barrel-shaped upper central incisors that erupt during the 6th yr of life; (2) abnormal enamel, which results in a notch along the biting surface; and (3) **mulberry molars**, abnormal 1st lower (6 yr) molars, characterized by a small biting surface and an excessive number of cusps. Defects in enamel formation lead to repeated caries and eventual tooth destruction.

A **saddle nose** (Fig. 200–4), a depression of the nasal root, is a result of syphilitic rhinitis that destroys the adjacent bone and cartilage. A perforated nasal septum is an associated abnormality. **Rhagades** are linear scars that extend in a spokelike pattern from previous mucocutaneous fissures of the mouth, anus, and genitalia.

Juvenile paresis, an uncommon latent meningovascular infection, typically presents during adolescence with behavioral changes, focal seizures, or loss of intellectual function. **Juvenile tabes** with spinal cord involvement and cardiovascular involvement with aortitis are extremely rare.

Figure 200-2 The mucocutaneous rash of congenital syphilis.

Other late manifestations of congenital syphilis may represent a hypersensitivity phenomenon. These include unilateral or bilateral interstitial keratitis with symptoms such as intense photophobia and lacrimation, followed within weeks or months by corneal opacification and complete blindness. Less common ocular manifestations include choroiditis, retinitis, vascular occlusion, and optic atrophy. Eighth nerve deafness may be unilateral or bilateral, appears at any age, presents initially as vertigo and high-tone hearing loss, and progresses to permanent deafness. The **Clutton joint** represents a unilateral or bilateral synovitis involving the lower extremities (usually the knee), which presents as painless joint swelling with sterile synovial fluid; spontaneous remission usually occurs after a period of several weeks. Soft tissue gummas (identical to those of acquired disease) and paroxysmal cold hemoglobinuria are rare hypersensitivity phenomena.

Diagnosis.

Diagnosis of primary syphilis is made with certainty when *T. pallidum* is demonstrated by dark-field microscopy or direct immunofluorescence on specimens from skin lesions, placenta, or umbilicus. However, serologic tests for syphilis are the principal means for diagnosis.

Nontreponemal tests, such as the **Venereal Disease Research Laboratory (VDRL)** and **rapid plasma reagin (RPR)** tests, detect antibodies against a cardiolipin-cholesterol-lecithin complex, not specific for syphilis. The quantitative results of these nontreponemal tests tend to correlate with disease activity and therefore are helpful in screening. Titers elevate when disease is active (including treatment failure or reinfection) and decline

Figure 200-3 Hutchinson teeth as a late manifestation of congenital syphilis.

Figure 200-4 Saddle nose in a newborn with congenital syphilis.

when treatment is adequate. Serum usually becomes nonreactive in the nontreponemal tests within 1 yr of adequate therapy for primary syphilis and within 2 yr of treatment for secondary disease. In congenital infection, these tests become nonreactive within a few months after adequate treatment. Certain conditions such as autoimmune diseases may give false-positive VDRL results in the serum (but not in the CSF), although false-positive results are less common because of the introduction of purified cardiolipin-lecithin-cholesterol antigen. Pregnancy itself does not give a false-positive VDRL result; all positive maternal serologic tests for syphilis, regardless of the titer, necessitate thorough investigation.

Treponemal tests, which measure antibody specific for *T. pallidum*, include the *T. pallidum* immobilization test (TPI), the fluorescent treponemal antibody absorption test (FTA-ABS), and the microhemagglutination assay for antibodies to *T. pallidum* (MHA-TP). Treponemal tests are used as confirmatory testing of positive results from the nontreponemal antibody tests. The MHA-TP has few false-positive test results (<1% of healthy persons) and is the treponemal test used by most clinical laboratories. Treponemal antibody titers become positive soon after initial infection and usually remain positive for life, even with adequate therapy. These antibody titers do not correlate with disease activity and are not quantified. They are useful for diagnosis of a first episode of syphilis and for distinguishing false-positive results of nontreponemal antibody tests but are of limited usefulness in the evaluation of response to therapy and possible reinfections.

There is limited cross-reactivity of treponemal antibody tests with the causative organisms of Lyme disease *(Borrelia burgdorferi)*, yaws (*T. pallidum* subsp. *pertenue*), endemic syphilis (*T. pallidum* subsp. *endemicum*), and pinta *(T. carateum)*. Only venereal syphilis *(T. pallidum)* and Lyme disease are found in the United States. The nontreponemal tests (VDRL, RPR) are uniformly nonreactive in Lyme disease.

Tests for IgM antibodies have been developed, including FTA-ABS 19S-IgM, IgM capture enzyme-linked immunosorbent assay, and Western immunoblotting assays, but these have been relatively insensitive and are not generally available. Tests for *T. pallidum* using polymerase chain reaction (PCR) amplification are also being developed.

The interpretation of nontreponemal and treponemal serologic tests in the newborn may be confounded by maternal IgG antibodies that are transferred to the fetus. Passively acquired antibody is suggested by neonatal titer at least fourfold (i.e., a two-tube dilution) less than the maternal titer. This can be verified by gradual decline in antibody in the infant, usually becoming undetectable by 3–6 mo of age.

The diagnosis of neurosyphilis in acquired disease is made by demonstrating pleocytosis and increased protein in the CSF, and

a positive CSF VDRL along with neurologic symptoms. The CSF VDRL is very specific but relatively insensitive (22–69%) for neurosyphilis.

Dark-field microscopy of scrapings from primary lesions or congenital or secondary lesions can reveal *T. pallidum*, often before serology becomes positive, but this technique is usually not available in clinical practice. Similarly, rabbit infectivity testing, used for measuring the sensitivity of investigational tests such as PCR and Western immunoblotting, is not widely available. Placental examination by gross and microscopic techniques can be useful in the diagnosis of congenital syphilis. The

disproportionately large placentas are characterized histologically by focal proliferative villitis, endovascular and perivascular arteritis, and focal or diffuse immaturity of placental villi.

CONGENITAL SYPHILIS.

Symptomatic infants should be thoroughly evaluated and treated. Asymptomatic infants considered at risk for congenital syphilis because the maternal nontreponemal and treponemal serology is positive should be evaluated if (1) maternal treatment was inadequate, unknown, or undocumented; (2) maternal treatment was =30 days before delivery; (3) the mother was treated with erythromycin or other nonpenicillin regimen; or (4) the maternal nontreponemal titers did not decrease sufficiently to demonstrate a cure (fourfold or greater). If the maternal treatment was adequate and =1 mo before delivery, the infant's positive nontreponemal test represents passively acquired antibody and the infant does not need treatment at delivery, but follow-up serology should be obtained. If the maternal evaluation is unable to be completed, these infants must be assumed to be infected and treated.

The diagnosis of neurosyphilis in the newborn with syphilitic infection is difficult owing to the poor sensitivity of the CSF VDRL in this age group and the lack of CSF abnormalities. In general, a positive CSF VDRL in a newborn warrants treatment for neurosyphilis, even though it might reflect passive transfer of antibodies from serum to CSF. More importantly, it is now accepted that all infants with a presumptive diagnosis of congenital syphilis should be treated with regimens effective for neurosyphilis because this cannot be reliably excluded.

The Centers for Disease Control and Prevention (CDC) recommends that infants be treated if (1) they were born to mothers who had untreated syphilis at delivery; (2) there is evidence of maternal relapse or reinfection; (3) there is physical evidence of active disease; (4) there is radiologic evidence of syphilis; (5) there is a reactive CSF VDRL or, for infants born to seropositive mothers, an abnormal CSF white blood cell count or protein, regardless of CSF serology; or (6) a serum quantitative nontreponemal serologic titer in the infant is at least fourfold greater than the mother's titer.

Treatment.

T. pallidum is extremely sensitive to penicillin, and there is no evidence of emerging penicillin resistance. Penicillin remains the drug of choice for treatment of syphilis (Table 200–1). A concentration 0.018?µg/mL (0.03?U/mL) of penicillin is needed to ensure killing of spirochetes in serum and CSF. Although nonpenicillin regimens are available to the penicillin-allergic patient, desensitization followed by standard penicillin therapy is the most reliable strategy. An acute systemic febrile reaction, the Jarisch-Herxheimer reaction, with exacerbation of lesions, occurs in 15–20% of all patients with acquired or congenital syphilis who are treated with penicillin. It is not an indication for discontinuation of penicillin therapy.

ACQUIRED SYPHILIS.

Primary, secondary, and early latent disease are treated with a single dose of benzathine penicillin G (50,000?units/kg IM; maximum: 2.4?million units). Nonpregnant penicillin-allergic patients without neurosyphilis may be treated with either doxycycline (100?mg PO bid for 2 wk) or tetracycline (500?mg PO qid for 2 wk).

Patients who are also infected with HIV are at increased risk for neurologic complications and have higher rates of treatment failures. The CDC guidelines recommend the same treatment of primary and secondary syphilis as for non–HIV-infected persons, but some experts recommend three weekly doses of benzathine penicillin G. HIV-infected patients with late latent syphilis or latent syphilis of unknown duration should have a CSF evaluation for neurosyphilis before treatment.

Incubating syphilis may be effectively treated with the currently recommended penicillin regimens for gonorrhea, and all patients treated for gonorrhea should have serologic testing for syphilis at the time of treatment and at follow-up 6–8 weeks later. Therapy with ampicillin, amoxicillin, or ceftriaxone is probably also effective. Spectinomycin therapy will not cure incubating syphilis. Because of the high risk of acquiring infection, “prophylactic treatment” should be given to sexual contacts of persons with infectious syphilis within the preceding 3 mo, regardless of serology. Three additional elements of syphilis therapy are obligatory: (1) Follow-up serology should be performed on treated individuals to establish adequacy of therapy; (2) sexual contacts should be identified and treated; and (3) testing for other sexually transmitted diseases, including HIV, should be performed on all patients.

SYPHILIS IN PREGNANCY.

When clinical or serologic findings suggest active infection or when the diagnosis of active syphilis cannot be excluded with certainty, treatment is indicated. Patients should be treated with the penicillin regimen appropriate for the woman's stage of syphilis. Women who have been adequately treated in the past do not require additional therapy unless quantitative serology suggests evidence of reinfection

TABLE 200-1 -- **Treatment of Syphilis**

Stage	Treatment and Dosage	Alternatives
Primary, secondary, or early latent (<1 yr)	Penicillin G benzathine (2.4 million U IM, in one dose) For children: Penicillin G benzathine (50,000?U/kg IM, up to the adult dose in a single dose)	Tetracycline (500?mg PO qid for 2 wk) or doxycycline (100?mg PO bid for 2 wk) or erythromycin (500?mg PO qid for 2 wk)
Late latent (>1 yr), latent of unknown duration, or tertiary (gumma or cardiovascular syphilis)	Penicillin G benzathine (2.4 million U IM) weekly for 3 doses	Tetracycline (500?mg PO qid for 4 wk) or doxycycline (100?mg PO bid for 4 wk)

Neurosyphilis	Aqueous crystalline penicillin G (12–24 million U/24?hr IV given as 2.4 million U every 4?hr) for 10–14 days For children: Aqueous crystalline penicillin G (200,000–300,000?U/kg every day IV, given every 4–6?hr) for 10–14 days	Penicillin G procaine (2.4 million U/day IM) *plus* probenicid (500?mg PO qid). Both for 10–14 days
Congenital syphilis	Aqueous crystalline penicillin G (100,000–150,000?U/kg/ 24?hr, given as 50,000?U/kg IV every 12?hr for the first 7 days and every 8?hr thereafter) for 10–14 days or Procaine penicillin G (50,000?U/kg IM daily in a single dose) for 10–14 days	

(fourfold elevation in titer). Doxycycline and tetracycline should not be administered during pregnancy, and erythromycin does not effectively treat fetal infection.

CONGENITAL SYPHILIS.

Adequate maternal therapy should eliminate the risk of congenital syphilis. All infants born to mothers with syphilis should be followed up until nontreponemal serology is negative. The infant should be treated if there is an uncertainty about the adequacy of the mother's treatment.

Current recommendations for treatment of congenital syphilis include regimens of aqueous penicillin G (100,000–150,000?U/kg/24?hr divided q 12?hr IV for the first wk of life, and q 8?hr thereafter) or procaine penicillin G (50,000?U/kg IM once daily) given for 10 days. Higher concentrations of penicillin are achieved in the CSF of infants treated with intravenous aqueous penicillin G than in those treated with intramuscular procaine penicillin. Both penicillin regimens are still recognized as adequate therapy for congenital syphilis. Treated infants should be followed up serologically to confirm decreasing nontreponemal antibody titers.

Prevention.

Testing is indicated at any time for persons with suspicious lesions, a history of recent sexual exposure to a person with syphilis, or diagnosis of another sexually transmitted infection, including HIV infection.

CONGENITAL SYPHILIS.

Routine prenatal screening for syphilis remains the most important factor in the identification of infants at risk for development of congenital syphilis and is legally required at the beginning of prenatal care in all states. In pregnant women without optimal prenatal care, serologic screening for syphilis should be performed at the time pregnancy is diagnosed. Any woman who is delivered of a stillborn infant =20 wk of gestation should be tested for syphilis. In communities and populations with a high prevalence of syphilis, or for patients at high risk, testing should be performed at least two additional times, at the beginning of the third trimester (28 wk) and at delivery. Some states mandate repeat testing at delivery for all women. Women at high risk for syphilis should possibly be screened more frequently, either monthly or pragmatically because of inconsistent prenatal care, at every medical encounter because they may have repeat infections during pregnancy or reinfection late in pregnancy.

No newborn should leave the hospital without the maternal serologic status having been determined at least once during pregnancy. In states conducting newborn screening for syphilis, both the mother's and infant's serologic results should be known before discharge. Testing of the mother's serum is preferred to testing cord blood or the infant's serum because the titers are frequently lower in the infant and may be nonreactive if the mother was infected late in pregnancy.

Chapter 201 - Nonvenereal Treponemal Infections

Parvin Azimi

Several variants of nonvenereal or endemic treponematoses are recognized by their geographic distribution. These diseases, which include yaws, bejel (or endemic syphilis), and pinta, are caused by spirochetes belonging to the genus *Treponema* that are morphologically and immunologically identical to *T. pallidum* and extremely sensitive to penicillin. They cause diseases that are differentiated primarily on the basis of clinical findings. Yaws is the most common of the nonvenereal spirochetal diseases.

201.1 Yaws (*Treponema pertenue*)

Yaws is a chronic relapsing infection involving the skin and bony structures caused by the spirochete *T. pertenue*, which cannot be differentiated microscopically or serologically from *T. pallidum*. It is found in the warm, humid tropical regions of Africa, Asia, South America, and Oceania. Almost all cases occur in children. A high percentage of the population is infected in endemic areas.

T. pertenue cannot penetrate intact skin and is transmitted by direct contact from an infected lesion through a skin abrasion or laceration. Transmission is facilitated by overcrowding and poor personal hygiene. The initial papular lesion, the “mother yaw,” occurs 2–8 wk after inoculation. The papule develops into a raised raspberry-like papilloma, which is often associated with regional lymphadenopathy. Secondary lesions erupt before or after the ulceration and healing of the mother yaw. With the healing of the mother yaw, there is hypopigmented scar formation. Secondary papillomas may appear anywhere and can be associated with lymphadenopathy, anorexia, and malaise. Ulcerated lesions are covered by exudates containing treponemes. Secondary lesions heal without scarring, but relapses are common within 5 yr after the primary lesion.

The lesions and exacerbations are often associated with bone pain and underlying periostitis or osteomyelitis, especially in the fingers, nose, and tibia. After the initial period of clinical activity, the patient enters a 5–10 yr period of latency. This is followed by the appearance of tertiary lesions at puberty, which are often solitary and destructive. These present as painful papillomas on the hands and feet, gummatous skin ulcerations, or osteitis. Bony destruction and deformity are common, as are juxta-articular nodules, depigmentation, and painful hyperkeratosis (“dry crab yaws”)

of the palms and soles.

Diagnosis depends on the clinical manifestations of the disease in an endemic area. Dark-field examination of cutaneous lesions and serologic tests for syphilis, both treponemal and nontreponemal, are confirmatory.

Treatment of patients and all contacts consists of a single dose of benzathine penicillin G (1.2 million U IM), which cures the lesions of active yaws, renders them noninfectious, and prevents relapse. Eradication of yaws from endemic foci may be accomplished by treating the entire population with penicillin. Patients allergic to penicillin may be treated with erythromycin or tetracycline.

201.2 Bejel (Endemic Syphilis) (*Treponema pallidum* subsp. *endemicum*)

Bejel, or endemic syphilis, affects children living in the Saharan regions of Africa and the Middle East. Infection with *T. pallidum* subsp. *endemicum* follows penetration of the spirochete through traumatized skin or mucous membranes. In experimental infections, a primary papule forms at the inoculation site after an incubation period of 3 wk; in human infections a primary lesion is almost never visualized.

The *clinical manifestations* of the secondary stage are confined to the skin and mucous membranes and consist of highly infectious mucous patches on the oral mucosa and condyloma-like lesions on the moist areas of the body, especially the axilla and anus. These mucocutaneous lesions resolve spontaneously over a period of several months, but recurrences are common. The secondary stage is followed by a variable latency period before the onset of late or tertiary bejel. The late complications, identical to those of yaws, include gumma formation in skin, subcutaneous tissue, and bone, resulting in painful destructive ulcerations, swelling, and deformity.

Diagnosis is suspected on epidemiologic and clinical grounds and is confirmed either by dark-field examination of cutaneous lesions or by serologic tests for syphilis, both treponemal and nontreponemal (Chapter 200).

Differentiation from venereal syphilis is extremely difficult in an endemic area. Bejel can be suspected by the absence of a primary chancre and lack of involvement of the central nervous system and cardiovascular system during the late stage.

Treatment of early injection consists of a single dose of benzathine penicillin G (1.2 million U IM); late infection is treated with 3 injections of the same dose at intervals of 7 days. Patients allergic to penicillin may be treated with erythromycin or tetracycline.

201.3 Pinta (*Treponema carateum*)

Pinta is a chronic, nonvenereally transmitted infection caused by *Treponema carateum*, a spirochete morphologically and serologically indistinguishable from other human treponemes. The disease is endemic in Mexico, Central America, South America, and parts of the West Indies. Infection follows direct inoculation of the treponeme through abraded skin. After a variable incubation period of days, a primary lesion appears at the inoculation site as a small asymptomatic erythematous papule resembling localized psoriasis or eczema. The regional lymph nodes are often enlarged, and spirochetes can be visualized on dark-field examination of skin scrapings or of the involved lymph nodes. After a period of enlargement, the primary lesion disappears. Secondary lesions follow within 6–8 mo and consist of small macules and papules on the face, scalp, and other exposed portions of the body. These pigmented lesions are scaly and nonpruritic and may coalesce to form large plaquelike elevations resembling psoriasis. In the late stage, atrophic and depigmented lesions develop on the hands, wrists, ankles, feet, face, and scalp. Hyperkeratosis of palms and soles is uncommon. *Diagnosis* is confirmed by dark-field examination of early lesions and a positive serologic test for syphilis. *Treatment* consists of a single dose of benzathine penicillin G (1.2 million U IM). Tetracycline and erythromycin are alternatives for patients allergic to penicillin.

Chapter 202 - Leptospira

Parvin Azimi

Etiology.

Leptospirosis is caused by spirochetes of the genus *Leptospira* and is the most widespread zoonosis in the world. The organisms are aerobic bacteria, 6–20?µm long and 0.1?µm wide with a terminal hook at one or both ends. They can be visualized by dark-field examination and by silver staining. Leptospires are cultured in liquid media; growth is slow on primary isolation and may require up to 13 weeks. Pathogenic leptospires have historically been classified as a single species, *Leptospira interrogans*, which includes more than 200 distinct serovars that have been useful for characterizing the epidemiology. Nonpathogenic leptospires were classified as *L. biflexa*, which has more than 60 serovars. More than 200 pathogenic serovars are recognized, making up the 23 serogroups. A single serovar may produce a variety of distinct syndromes, and a single clinical manifestation may be caused by multiple serotypes.

Epidemiology.

Leptospirosis is a zoonosis of worldwide distribution with most human cases in tropical and subtropical developing countries. Leptospires infect many species of domestic and feral animals, including pets and livestock, and have been isolated also from birds, fish, and reptiles. The rat is the principal source of human infection. Other important animal reservoirs include dogs, cats, livestock, and wild animals. Animal infection varies from inapparent to fatal. Once infected, animals excrete spirochetes in urine for an extended period of time. Leptospire survival outside the animal host is dependent on the moisture content, temperature, and pH of the soil or water into which they are shed. The majority of human cases worldwide result from occupational exposure to water or soil contaminated with rat urine. Occupational groups with a high incidence of leptospirosis include agricultural workers, veterinarians, abattoir workers, meat inspectors, rodent control workers, laboratory workers, and workers in other occupations that require contact with animals. In the United States, the major animal reservoir is the dog, and contact with spirochetes is often associated with recreational activities that result in contact with contaminated soil or water during the summer months. Transmission via contaminated water, animal bites, and directly from person-to-person, which is rare, has been reported.

Pathogenesis.

Leptospires enter humans through abrasions and cuts in the skin or through mucous membranes. After penetration, leptospires circulate in the bloodstream and spread to all organs of the body. The primary lesion caused by leptospires is damage to the endothelial lining of small blood vessels with resultant ischemic damage to the liver, kidneys, meninges, and muscles.

Clinical Manifestations.

The spectrum of human leptospirosis ranges from asymptomatic infection to a severe syndrome of multiorgan dysfunction with high mortality. The clinical presentation is biphasic. After an incubation period of 7–12 days, the initial or **septicemic phase** begins in which leptospires can be isolated from the blood, cerebrospinal fluid (CSF), and other tissues. Initial symptoms, which last 2–7 days, may be followed by a brief period of well-being and the second symptomatic or **immune phase**. The immune phase is associated with the appearance of circulating antibody, the disappearance of organisms from the blood and CSF, and the appearance of additional signs and symptoms associated with localization of leptospires in the tissues. Despite the presence of circulating antibody,

leptospires may persist in the kidney, urine, and aqueous humor. The immune or leptospiruric phase may last for several weeks.

Most cases of human leptospirosis are subclinical or very mild, with inapparent infection particularly common in high-risk occupational groups such as farmers and their families. Symptomatic infection may present as an acute febrile illness with nonspecific signs and symptoms (70%), as aseptic meningitis (20%), or as hepatorenal dysfunction (10%). The onset is typically sudden, and the illness tends to follow a biphasic course (Fig. 202–1).

ANICTERIC LEPTOSPIROSIS.

The onset of the septicemic phase is abrupt, with fever, shaking chills, lethargy, severe headache, malaise, nausea, vomiting, and severe, often debilitating myalgia. Some patients have bradycardia and hypotension but circulatory collapse is uncommon. Additional physical findings include extreme muscle tenderness, which is most prominent in the lower extremities, the lumbosacral spine, and the abdomen. Conjunctival suffusion with photophobia and orbital pain (in the absence of chemosis and purulent exudate), generalized lymphadenopathy, and hepatosplenomegaly may also be present. A transient rash, lasting <24?hr, may occur in 10% of cases, and usually consists of a truncal erythematous maculopapular rash but may be urticarial, petechial, purpuric, or desquamating. Less common manifestations include pharyngitis, pneumonitis, arthritis, carditis, cholecystitis, and orchitis. The second or immune phase may follow a brief asymptomatic interlude and is characterized by recurrence of fever and aseptic meningitis. Despite abnormal CSF profiles in 80% of

infected children, only 50% have meningeal manifestations. CSF abnormalities include a modest elevation in pressure, a pleocytosis with polymorphonuclear leukocytes initially followed by mononuclear predominance and rarely exceeding 500 cells/mm^3 , normal or slightly elevated protein levels, and normal glucose values. Encephalitis, cranial and peripheral neuropathies, papilledema, and paralysis are uncommon. Uveitis may occur during this phase; it can be unilateral or bilateral and is usually self-limited, rarely resulting in permanent visual impairment. Symptoms referable to the central nervous system resolve spontaneously within about 1 wk, with almost no mortality.

ICTERIC LEPTOSPIROSIS (WEIL SYNDROME).

This severe form of leptospirosis occurs in <10% of cases and is less common in children and more common in persons older than 30 yr of age. The initial manifestations are similar to those described for anicteric leptospirosis. The immune phase, however, is distinctive, being characterized by clinical and laboratory evidence of hepatic and renal dysfunction. In fulminating cases, hemorrhagic phenomena and cardiovascular collapse also occur. Hepatic abnormalities

Figure 202-1 Stages of anicteric and icteric leptospirosis. Correlation between clinical findings and presence of leptospires in body fluids. (Reprinted with permission from Feigin RD, Anderson DC: Human leptospirosis. *CRC Crit Rev Clin Lab Sci* 1975;5: 413–67. Copyright CRC Press, Inc., Boca Raton, FL.)

include right upper quadrant pain, hepatomegaly, direct and indirect hyperbilirubinemia, and modestly elevated serum levels of hepatic enzymes. The jaundice is not the result of hepatocellular necrosis, and liver function usually returns to normal after recovery. Renal manifestations are common; all patients have abnormal findings on urinalysis (hematuria, proteinuria, and casts), and azotemia is common, often associated with oliguria or anuria. Acute renal failure occurs in 16–40% of cases and is the principal cause of death. Abnormal electrocardiograms are present in 90% of cases, but congestive heart failure is uncommon. Hemorrhagic manifestations are rare but when present may include epistaxis, hemoptysis, and gastrointestinal and adrenal hemorrhage. Thrombocytopenia occurs in >50% of cases, but is transient and does not result from disseminated intravascular coagulation. Mortality is 5–15%.

Diagnosis.

Leptospirosis should be considered in the differential diagnosis of any acute febrile illness when there is a history of direct contact with animals or with soil or water contaminated with animal urine, and especially when the onset is abrupt with chills, fever, severe myalgias, conjunctival suffusion, headache, nausea, and vomiting.

The diagnosis is established most often by serologic testing, and less frequently by isolation of the infecting organism from clinical specimens. Serologic tests for *Leptospira* include genus-specific and serogroup-specific tests. The reference method is the **microscopic agglutination test**, which is a serogroup-specific assay using live antigen suspensions of leptospiral serovars. The test is read by dark-field microscopy for agglutination, and titers are determined. This test requires live cultures of all serovars for use as antigens. A fourfold or greater increase in titer in paired sera confirms the diagnosis. Agglutinins usually appear by the 12th day of illness and reach a maximum titer by the 3rd wk. Low titers may persist for years. Approximately 10% of infected persons do not have detectable agglutinins, presumably because available antisera do not identify all *Leptospira* serotypes. An adaptation of the agglutination test is the use of antigens from killed or formalinized organisms; titer results are slightly lower and more cross-reactions occur. Enzyme-linked immunosorbent assay (ELISA) methods, including an IgM-specific dot-ELISA test, have also been developed.

Warthin-Starry silver staining and immunofluorescent and immunohistochemical methods permit identification of leptospires in infected tissue or body fluids. Spirochetes may also be demonstrated by phase-contrast or dark-field microscopy, but these are insensitive.

Unlike other pathogenic spirochetes, leptospires are easily cultured on commercially available media containing rabbit serum or bovine serum albumin and long-chain fatty acids. Repeated blood cultures in the 1st wk of infection with very small inocula of blood are recommended. A small inoculum (i.e., one drop of blood in 5?mL of medium) is used to minimize growth inhibitory factors. Leptospires can be recovered from the blood or CSF during the first 10 days of illness and from urine after the 2nd wk. The number of leptospires in clinical specimens is small and their growth rate is slow; leptospires may be seen in several days, although cultures may not become positive for 2–4 mo. Prolonged incubation is required.

Treatment.

Despite the in vitro sensitivity of *Leptospira* to penicillin and tetracycline and the efficacy of these agents in treating experimental infection, their effectiveness in human leptospirosis remains controversial. It appears that initiation of treatment before the 7th day will probably shorten the clinical course and decrease the severity of the infection, and therefore treatment with penicillin or tetracycline (in children 9 yr of age or older) should be instituted as soon as the diagnosis is suspected. Parenteral penicillin G (6–8 million U/m^2 /24?hr divided q 4?hr IV for 7 days) is recommended, with tetracycline (10–20?mg/kg/24?hr divided q 6?hr PO or IV for 7 days) as an alternative for patients allergic to penicillin.

Prevention.

Prevention of human leptospirosis is facilitated by instituting rodent control measures and avoiding contaminated water and soil. Immunization of livestock and family pets has been recommended as a means of eliminating animal reservoirs, but these programs have met with limited success. A formalin-killed polyvalent human vaccine has been used in “at risk” occupation groups in Europe and Asia; however, there have been no clinical trials to determine its efficacy. Leptospirosis has been prevented in American servicemen stationed in the tropics by administering doxycycline (200?mg PO once a week) as prophylaxis. This schedule may be similarly effective for the traveler entering a highly endemic area for a limited period

of time.

Chapter 203 - Relapsing Fever (*Borrelia*)

Parvin Azimi

Etiology.

Relapsing fever is an uncommon arthropod-borne infection characterized by recurrent episodes of fever. It is caused by spirochetes of the genus *Borrelia*, a fastidious microorganism with worldwide distribution that is transmitted to humans by lice or ticks.

Epidemic relapsing fever, or **louse-borne fever**, is caused by *B. recurrentis* and is transmitted from person to person by *Pediculus humanus*, the human body louse. After ingestion of an infective blood meal by the louse, the spirochetes penetrate its midgut, migrate to and multiply within the hemolymph, and remain viable throughout its lifespan (several weeks). Human infection occurs as a result of crushing lice during scratching, allowing infected hemolymph to enter through the abraded skin.

Endemic relapsing fever, or **tick-borne fever**, is caused by several species of *Borrelia* and is transmitted to humans by *Ornithodoros* ticks. *B. hermsii* is the common species in the western United States, and *B. dugesi* is the major cause of disease in Mexico and Central America. After ingestion of an infective blood meal, spirochetes invade all tissues of their arthropod hosts, including the salivary glands and reproductive tract. The latter permits transovarian passage of infected spirochetes, perpetuating arthropod infection in successive generations. Human infection occurs when saliva, coxal fluid, or excrement is released by the tick during feeding, thereby permitting spirochetes to penetrate the skin and mucous membranes.

Epidemiology.

Louse-borne epidemic relapsing fever tends to occur in epidemics, often in association with typhus. Epidemics are associated with war, poverty, famine, and poor personal hygiene. This form of relapsing fever occurs more commonly during the winter. The major endemic focus of the disease is the highlands of Ethiopia.

Ornithodoros ticks, which transmit endemic relapsing fever, are distributed worldwide, including the western United States, prefer warm, humid environments

and high altitudes, and are found in rodent burrows, caves, and other nesting sites. Rodents are the principal reservoirs. Infected ticks gain access to human dwellings on the rodent host. Human contact is often unnoticed because these soft ticks, unlike the hard ticks, which attach and feed over a period of days, are nocturnal feeders, have a painless bite, and detach immediately after a short blood meal.

Pathogenesis.

The cyclic nature of relapsing fever is explained by the ability of *Borrelia* organisms to continually undergo antigenic (phase) variation. Multiple variants evolve simultaneously during the first relapse, with one type becoming predominant. Spirochetes isolated during the primary febrile episode differ antigenically from those recovered during a subsequent relapse. During febrile episodes, spirochetes enter the bloodstream, induce the development of specific IgM and IgG antibody, and undergo agglutination, immobilization, lysis, and phagocytosis. During remission, *Borrelia* spirochetes may remain in the bloodstream, but spirochetemia is insufficient to produce symptoms. The number of relapses in untreated patients depends on the number of antigenic variants of the infecting strain.

Clinical Manifestations.

Relapsing fever is characterized by periods of fever lasting 2–9 days, separated by afebrile periods of 2–7 days. Louse-borne disease has a longer incubation period, longer periods of pyrexia, fewer relapses, and longer remission periods than tick-borne disease. The incubation period of tick-borne disease is usually 8 days, with a range of 5–15 days. Each form of relapsing fever is associated with sudden onset of high fever, lethargy, headache, photophobia, nausea, vomiting, myalgia, and arthralgia. Additional symptoms may appear later and include abdominal pain, a productive cough, and mild respiratory distress. Bleeding manifestations are common and include epistaxis, hemoptysis, hematuria, and hematemesis. A diffuse, erythematous, macular, or petechial rash may develop over the trunk and shoulders. This rash is more common in louse-borne fever (25%), is of 1–2 days' duration, and occurs almost exclusively during the end of the primary febrile episode. There may also be lymphadenopathy, pneumonia, and splenomegaly. Hepatic tenderness associated with hepatomegaly is a common sign, with jaundice in half of affected children. Central nervous system manifestations may be the principal feature of late relapses in tick-borne disease; they include lethargy, stupor, meningismus,

convulsions, peripheral neuritis, focal neurologic deficits, and cranial nerve paralysis. Severe manifestations include myocarditis, hepatic failure, and disseminated intravascular coagulopathy.

The initial symptomatic period characteristically ends with a crisis in 2–9 days, marked by abrupt diaphoresis, hypothermia, hypotension, bradycardia, profound muscle weakness, and prostration. In untreated patients, the first relapse occurs within 1 wk, followed by usually 3 but up to 10 relapses with symptoms during each relapse becoming milder and shorter as the afebrile remission period lengthens.

Diagnosis.

Diagnosis depends on demonstration of spirochetes in thin or thick blood smears stained with Giemsa or Wright's stain. During afebrile remissions, spirochetes are not found in the blood. Serologic tests, such as enzyme immunoassay and Western blotting, are not standardized and generally not available. Tick-borne disease produces a serologic cross reaction with other spirochetes, including *Borrelia burgdorferi*, the agent of Lyme disease.

Treatment.

Oral or parenteral tetracycline is the drug of choice for louse-borne and tick-borne relapsing fever. For older children and young adults, tetracycline (500?mg PO q 6?hr) for 10 days has been effective. Single-dose treatment with tetracycline (500?mg PO) or erythromycin is efficacious in adults, but experience in children is limited. In children younger than 12 yr of age, erythromycin (50?mg/kg/24?hr divided q 6?hr PO) for a total of 10 days is recommended. Penicillin and chloramphenicol are also effective.

Resolution of each febrile episode either by natural crisis or as a result of antimicrobial treatment is usually accompanied within 2?hr by the Jarisch-Herxheimer reaction, which is associated with clearing of the spirochetemia. Attempts to control this reaction by prior treatment with corticosteroids or antipyretics have met with limited success.

Prognosis.

With adequate therapy, the mortality rate for relapsing fever is <5%. A majority of patients recover from their illness with or without treatment after the appearance of anti-*Borrelia* antibodies, which agglutinate, kill, or opsonize the spirochete.

Prevention.

No vaccine is available. Disease control requires avoidance or elimination of the arthropod vectors. In epidemics of louse-borne disease, dissemination can be prevented by good personal hygiene and delousing of persons, dwellings, and clothing with commercially available insecticides. The risk of tick-borne disease can be minimized in endemic areas by maintaining rodent-free dwellings.

Chapter 204 - Lyme Disease (*Borrelia burgdorferi*)

Eugene D. Shapiro

Lyme disease is the most common vector-borne disease in the United States. Although Lyme disease is a public health concern, extensive publicity as well as a very high frequency of misdiagnoses have resulted in a degree of anxiety about Lyme disease that is out of proportion to the actual morbidity that it causes.

Etiology.

Lyme disease is caused by the spirochete *Borrelia burgdorferi*, a fastidious, microaerophilic bacterium that replicates very slowly and requires special media for in vitro growth. *B. burgdorferi* is cylindrically shaped with a cell membrane that is covered by flagella and a loosely associated outer membrane. The three major outer-surface proteins—OspA, OspB, and OspC (which are highly charged basic proteins of molecular weights of about 31, 34, and 23?kd, respectively)—as well as the 41?kd flagellar protein, are important targets for the immune response. Differences in the molecular structure of *B. burgdorferi* strains, especially between isolates from Europe and the United States, are well documented. Clinical manifestations of Lyme borreliosis in Europe and in the United States, such as the greater frequency of radiculoneuritis in Europe, may be attributable to these differences.

Epidemiology.

Lyme disease has been reported from more than 50 countries. In 2000, there were 17,730 cases reported in the United States, with most cases in southern New England, the eastern parts of the Middle Atlantic states, and the upper Midwest, with a smaller endemic focus of Lyme disease along the Pacific coast (Fig. 204–1). In Europe, most cases occur in the

Figure 204-1 The approximate distribution of predicted risk for Lyme disease in the United States. The risk varies by the distribution of *Ixodes scapularis* and *I. pacificus*, the proportion of infected ticks for each species at each stage of the tick's life cycle, and the presence of grassy or wooded locations favored by white-tailed deer. (Figure from the Centers for Disease Control and Prevention.)

Scandinavian countries and in central Europe, especially Germany, Austria, and Switzerland. Estimates of the incidence of Lyme disease are complicated by passive systems for reporting of Lyme disease and the high frequency of misdiagnosis of this illness. In endemic areas, the reported annual incidence ranges from 20–100 cases/100,000 population, although this figure may be as high as 1,000 cases/100,000 population in hyperendemic areas such as Lyme, Connecticut. The reported incidence is highest among children 5–10 yr of age, which is almost twice as high as the incidence among older children and adults.

TRANSMISSION.

Lyme disease is a zoonosis caused by the transmission of *B. burgdorferi* to humans through the bite of an infected tick of the *Ixodes* species. In the eastern and midwestern United States, the vector is *Ixodes scapularis* (formerly known as *Ixodes dammini*), the black-legged tick that is commonly known as the deer tick, which is responsible for most cases of Lyme disease in the United States. The vector on the Pacific Coast is *Ixodes pacificus*, the western black-legged tick. *Ixodes* ticks have a 2-yr, three-stage life cycle. The larvae hatch in the early summer and are usually uninfected with *B. burgdorferi*. The tick may become infected at any stage of its life cycle by feeding on a host, usually a small mammal such as the white-footed mouse *(Peromyscus leucopus)*, which is a natural reservoir for *B. burgdorferi*. The larvae overwinter and emerge the following spring in the nymphal stage, which is the stage of the tick that is most likely to transmit the infection. The nymphs molt to adults in the fall. The females lay their eggs the following spring before they die, and the 2-yr life cycle begins again.

Several factors are associated with increased risk of transmission of *B. burgdorferi* from ticks to humans. The proportion of infected ticks varies by geographic area and for each stage of the tick's life cycle. In endemic areas in the northeastern and midwestern United States, 15–20% of nymphal ticks and 35–40% of the adult ticks are infected with *B. burgdorferi*. There are small foci in which the rate of infection of adult deer ticks is 60–80% or even higher. By contrast, *Ixodes pacificus* often feeds on lizards, which are not a competent reservoir for *B. burgdorferi*. Only 1–3% of these ticks, even in the nymphal and adult stages, are infected with *B. burgdorferi*. The risk of transmission of *B. burgdorferi* from infected *Ixodes* ticks is related to the duration of feeding. It takes hours for the mouthparts of ticks to implant fully in the host and much longer (days) for the tick to become fully engorged. Experiments in animals have shown that infected nymphal ticks must feed for =36–48?hr, and infected adults must feed for =48–72?hr, before the risk of transmission of *B. burgdorferi* becomes substantial. Most individuals who are bitten by a tick will recognize and remove the tick before the transmission of *B. burgdorferi* can occur. Persons with increased occupational, recreational, or residential exposure to tick-infested woods or fields (the preferred habitat of ticks) in endemic areas are at increased risk of developing Lyme disease.

Pathogenesis.

The skin is the initial target of infection by *B. burgdorferi*. Inflammation induced by *B. burgdorferi* leads to the development of the characteristic rash, erythema migrans. Early disseminated Lyme disease is caused by the spread of spirochetes, through the bloodstream, to tissues throughout the body. The spirochete adheres to the surfaces of a wide variety of different types of cells, which may be responsible for the involvement of many organs. Because the organism may persist in tissues for prolonged periods of time, symptoms may appear very late after initial infection.

The symptoms of early disseminated as well as of late Lyme disease are due to inflammation mediated by interleukin-1 and other lymphokines in response to the presence of the organism. It is likely that relatively few organisms actually invade the host, but cytokines serve to amplify the inflammatory response and lead to much of the tissue damage. The refractory symptoms of late Lyme disease may have an immunogenetic basis. Patients with the HLA-DR2, DR3, and DR4 allotypes may be genetically predisposed to develop chronic recurrent Lyme arthritis. These class II histocompatibility molecules located on macrophages and B cells are involved in the presentation of antigens to T-helper cells that initiate the immune response. Although rare (especially in children), in genetically susceptible individuals, *B. burgdorferi* may initiate an autoimmune response that causes persistent inflammation of the synovium and clinical symptoms long after the bacteria have been killed.

Histologically, Lyme disease is characterized by inflammatory lesions that contain both T and B lymphocytes, macrophages, plasma cells, and some mast cells. The erythema migrans rash consists of a moderately dense infiltrate of lymphocytes, plasma cells, and occasional macrophages, located around the small blood vessels of the upper dermis. Lyme myocarditis is a transmural myocarditis with widespread interstitial lymphocytic and plasma cell infiltrate. Similar infiltrates have been seen in the meninges and cerebral cortex. There are few reports of the histology of synovial tissue during the acute stages of Lyme arthritis. At this stage of the illness, the synovial fluid often has a marked predominance of polymorphonuclear cells, suggesting that the synovial tissue also will have a polymorphonuclear inflammatory infiltrate. By contrast, chronic, recurrent arthritis is characterized by a chronic hypertrophic synovitis. This nonspecific abnormality, also found in other disorders such as rheumatoid arthritis, is marked by hyperplasia of the synovial cells with varying degrees of lymphocytic infiltrates that sometimes form abortive germinal centers and follicles. Plasma cells are present at the periphery of the lymphoid aggregates. In advanced disease, neovascularization (a nonspecific response to chronic inflammation) may occur.

Clinical Manifestations.

The clinical manifestations of Lyme disease are divided into early and late stages. Early Lyme disease is further classified as early localized or early disseminated disease. Untreated patients may progressively develop clinical symptoms of each stage of the disease, or they may present with early disseminated or with late disease without apparently having had any symptoms of the earlier stages of Lyme disease.

EARLY LOCALIZED DISEASE.

The first clinical manifestation of Lyme disease is the typical annular rash, named **erythema migrans**. Although it usually occurs 7–14 days after the bite, the onset of

the rash has been reported from 3–32 days later. The initial lesion occurs at the site of the bite. The rash may be uniformly erythematous, or it may appear as a target lesion with central clearing; rarely, there may be central vesicular or necrotic areas. Occasionally the rash may be itchy or painful. The lesion can occur anywhere on the body, although the most common locations are the axilla, the periumbilical area, the thigh, and the groin. Erythema migrans may be associated with systemic features including fever, myalgia, headache, or malaise. Without treatment, the rash gradually expands (hence the name *migrans*) to an average diameter of 15?cm and remains present for at least 1–2 wk.

EARLY DISSEMINATED DISEASE.

In the United States, a substantial proportion (about 20%) of patients with acute *B. burgdorferi* infection develop secondary erythema migrans lesions, a common manifestation of early disseminated Lyme disease caused by hematogenous spread of the organisms to multiple skin sites. The secondary lesions, which may develop several days or even weeks after the first lesion, usually are smaller than the primary lesion and are often accompanied by fever, myalgia, headache, and malaise; conjunctivitis and lymphadenopathy also may develop. Occasionally, when the erythema migrans rash resolves, new evanescent lesions, which usually are small (1–3?cm), erythematous annular lesions that do not expand, continue to appear for several weeks. Other manifestations may include aseptic meningitis, with signs of meningeal irritation such as nuchal rigidity (and associated with

---

papilledema in about 25–35% of cases); uveitis; focal neurologic findings, especially cranioneuropathies; and, rarely, carditis, with varying degrees of heart block. Paralysis of the facial (7th) cranial nerve is relatively common in children and may be the initial or the only manifestation of Lyme disease. The paralysis usually lasts 2–8 wk and resolves completely in most cases. There is no evidence that the clinical course of the facial palsy is affected by antimicrobial treatment.

LATE DISEASE.

Arthritis, beginning weeks to months after the initial infection, is the usual manifestation of late Lyme disease. Arthritis typically involves the large joints, especially the knee, which is affected in >90% of cases, but any joint may be affected. The joint is swollen and tender but patients usually do not experience the exquisite pain that is typical of bacterial arthritis. Although it may last for several weeks, the joint swelling usually resolves within 1–2 wk before recurring, often in other joints. If the disease is not treated, the episodes of arthritis may increase in duration, sometimes lasting for months; but in most cases the disease eventually resolves, even in patients who are untreated and who have had many recurrences of arthritis.

Late manifestations of Lyme disease involving the central nervous system, sometimes termed **tertiary neuroborreliosis**, are rarely reported in children. In adults, chronic demyelinating encephalitis, polyneuritis, and impairment of memory have been attributed to Lyme disease.

CONGENITAL LYME DISEASE.

Although *B. burgdorferi* has been identified from several abortuses and from a few liveborn children with congenital anomalies, the placentas and the abortuses in which the spirochete was identified usually did not show histologic evidence of inflammation. No consistent pattern of fetal damage has been identified to suggest a clinical syndrome of congenital infection. Furthermore, studies conducted in endemic areas have indicated that there is no difference in the prevalence of congenital malformations among the offspring of women with serum antibodies against *B. burgdorferi* and the offspring of those without such antibodies. A survey of child neurologists in endemic areas found that none had seen a credible case of a child with congenital Lyme disease. If congenital Lyme disease does exist, it must be extremely rare.

Diagnosis.

The clinical manifestations of Lyme disease, other than erythema migrans, are not specific. The monoarticular or pauciarticular arthritis may mimic either an acute septic joint or other causes of arthritis in children, such as juvenile rheumatoid arthritis or rheumatic fever. Clinically, 7th nerve palsy due to Lyme disease is indistinguishable from idiopathic Bell palsy, and Lyme meningitis may mimic enteroviral meningitis. The diagnosis of erythema migrans may be difficult because the rash initially may be confused with nummular eczema, tinea, granuloma annulare, an insect bite, or cellulitis. However, the relatively rapid expansion of erythema migrans helps distinguish it from these other conditions.

Although attempts have been made to develop antigen-based diagnostic tests, including the polymerase chain reaction, all of these tests are experimental. None of the tests for *B. burgdorferi* antigens that have been adequately evaluated are sufficiently sensitive and specific to be clinically useful. Consequently, the confirmation of Lyme disease usually is based on the demonstration of antibodies to *B. burgdorferi* in the patient's serum.

SEROLOGY.

Specific IgM antibodies appear first, usually at 3–4 wk, peak at 6–8 wk, and subsequently decline, although a prolonged elevation of IgM antibodies sometimes occurs despite effective antimicrobial treatment. Consequently, the results of tests for specific IgM antibodies should not be used as an indicator of either active or recent infection. Specific IgG antibodies usually appear at 6–8 wk, peak after 4–6 mo, and may remain elevated indefinitely. The antibody response to *B. burgdorferi* may be abrogated in patients with early Lyme disease who are treated promptly with an effective antimicrobial agent, but in most patients IgG antibodies remain detectable for many years after treatment and clinical resolution of the illness.

Because the immunofluorescent antibody test requires subjective interpretation and is time consuming to perform, it has been replaced by enzyme-linked immunosorbent assays (ELISA) for the detection of antibodies against *B. burgdorferi*. The ELISA method sometimes produces false-positive results because of

cross-reactive antibodies to other spirochetal infections (e.g., syphilis, leptospirosis, or relapsing fever), to certain viral infections (e.g., varicella), against spirochetes that comprise part of the normal oral flora, and with certain autoimmune diseases (e.g., systemic lupus erythematosus).

Western blotting (i.e., immunoblotting) is also used as a diagnostic test for Lyme disease, although there is still some debate about its interpretation. For example, many people who do not have Lyme disease have antibodies against the 41-kd protein (the flagellar protein) of *B. burgdorferi*. Official recommendations for serologic tests for Lyme disease are to perform a quantitative test (such as ELISA) and a confirmatory Western immunoblot test if the ELISA result is either positive or equivocal.

The currently available serologic tests, especially widely used commercial kits, generally have only fair specificity. Use of these commercial diagnostic serologic tests will result in a high rate of misdiagnosis. In contrast, the serologic tests for Lyme disease performed by reference laboratories are relatively accurate. However, even with these tests, the predictive value of the result still depends primarily on the probability that the patient has Lyme disease based on the clinical and epidemiologic history and the physical examination (the “pretest probability”). With few exceptions, the pretest probability that a patient has Lyme disease will be very low in areas in which Lyme disease is rare. Even in areas with a high prevalence of Lyme disease, patients with *only* nonspecific signs and symptoms, such as fatigue, headache, or arthralgia, are not likely to have Lyme disease; virtually all positive serologic test results in such patients are false-positive results. Consequently, serologic tests for Lyme disease should not be ordered in such patients. Serologic tests for Lyme disease should only be obtained for patients with a relatively high (=20%) probability of having Lyme disease—that is, only in patients who have objective physical signs that are suggestive of Lyme disease, in whom the predictive value of a positive test result is high.

Even though a symptomatic patient has antibodies to *B. burgdorferi*, Lyme disease may not be the cause of the patient's symptoms. The test result may be falsely positive, or the patient may have been infected previously. Once serum antibodies to *B. burgdorferi* develop, they may persist for many years despite adequate treatment and clinical cure of the disease. Because some people who become infected with *B. burgdorferi* are asymptomatic, the background rate of seropositivity among patients who have never had clinically apparent Lyme disease may be substantial in endemic areas.

CULTURE.

The isolation of *B. burgdorferi* from a symptomatic patient is considered diagnostic of Lyme disease. Although *B. burgdorferi* has been isolated from blood, skin, cerebrospinal fluid (CSF), myocardium, and the synovium of patients with Lyme disease, the medium in which *B. burgdorferi* is cultured is expensive, it can take as long as 4 wk for the bacteria to grow in culture, and the frequency of isolation of *B. burgdorferi* from patients with active Lyme disease is low. It usually is necessary for patients to undergo an invasive procedure, such as a skin biopsy or a lumbar puncture, to obtain appropriate tissue or fluid for culture. *B. burgdorferi* has been identified with silver stains (Warthin-Starry or modified Dieterle) and with immunohistochemical stains (using monoclonal or polyclonal antibodies) in skin, synovial, and myocardial biopsy specimens. However, *B. burgdorferi* can be confused with normal tissue structures or it can be missed because it usually is present in low concentrations.

LABORATORY FINDINGS.

Routine laboratory tests rarely are helpful in diagnosing Lyme disease because the associated laboratory abnormalities usually are nonspecific. The peripheral white blood cell count may be either normal or elevated. The erythrocyte sedimentation rate usually is elevated. The white blood cell concentration in joint fluid may range from 25,000–125,000/mL, often with a preponderance of polymorphonuclear cells. When the central nervous system is involved, there usually is a mild pleocytosis with a lymphocytic predominance. The CSF protein level may be elevated, but the glucose concentration usually is normal.

Treatment.

No clinical trials of treatment for Lyme disease have been conducted in children. Recommendations for the treatment of children (Box 204–1) are extrapolated from studies of adults. Children younger than 8 yr of age should not be treated with doxycycline because it may cause permanent discoloration of their teeth. Patients who are treated with doxycycline should be alerted to the risk of developing dermatitis in sun-exposed areas while taking the medication. Cefuroxime is also licensed for the treatment of Lyme disease and is an alternative for persons who cannot take doxycycline and who are allergic to penicillin. Preliminary results with azithromycin have been disappointing. There is little need to use newer agents because the results of treatment with either amoxicillin or doxycycline have been good.

Some patients may develop a Jarisch-Herxheimer reaction soon after treatment is initiated. The manifestations of this reaction are increased temperature, sweats, and myalgia. These symptoms resolve spontaneously within 24–48?hr, although administration of nonsteroidal anti-inflammatory drugs often is beneficial. Nonsteroidal anti-inflammatory agents also may be useful in treating symptoms of early Lyme disease and of Lyme arthritis.

Fatigue, arthralgia, and myalgia, which may accompany or follow more specific symptoms and signs of Lyme disease but almost never are the sole presenting manifestations of Lyme disease, sometimes persist after treatment but generally resolve over a period of weeks to months. There is little evidence that

Box 204-1. Antimicrobial Treatment of Lyme Disease (*Lyme borreliosis*)

EARLY DISEASE

Erythema migrans and disseminated early disease without focal findings

Doxycycline, 100?mg twice daily for 14–21 days (do not use in children <8 yr)

or

Amoxicillin, 50?mg/kg/24?hr divided tid (maximum: 500?mg/dose) PO for 14–21 days

Preferred alternative agent for those who cannot take either amoxicillin or doxycycline is cefuroxime, 30?mg/kg/24?hr divided bid (maximum: 500?mg/dose) PO for 14–21 days. Another alternative is erythromycin, 30–50?mg/kg/24?hr divided qid (maximum: 250?mg/dose) PO for 14–21 days.

Carditis

For mild-moderate disease, treat as for erythema migrans for 21 days. For severe disease (e.g., third degree block), treat as for meningitis.

Palsy of the cranial nerves (including 7th nerve palsy)

If no clinical evidence of meningitis, treat as for erythema migrans for 21 days. Do not use corticosteroids.

Meningitis

Ceftriaxone, 50–80?mg/kg/24?hr in a single dose (maximum: 2?g) IV or IM for 14–28 days, or penicillin G, 200,000–400,000?U/kg/24?hr (maximum: 20 million units/24?hr) divided q 4?hr IV for 14–28 days

Ceftriaxone, 50–80?mg/kg/24?hr in a single dose (maximum: 2?g) IV or IM for 14–28 days, or penicillin G, 200,000–400,000?U/kg/24?hr (maximum: 20 million units/24?hr) divided q 4?hr IV for 14–28 days

LATE DISEASE

Arthritis

Initial treatment is the same as for erythema migrans except treatment is continued for 28 days. If symptoms fail to resolve after 2 mo or there is a recurrence, then give either a second course of an orally administered antimicrobial agent for 28 days or treat as for meningitis.

these symptoms are related to persistence of the organism. Because antibodies against *B. burgdorferi* persist after successful treatment, there is no reason to obtain follow-up serologic tests. There is also no evidence that either repeated or prolonged courses of antimicrobial agents hasten the resolution of such symptoms. Indeed, a National Institutes of Health–sponsored double-blind, randomized, placebo-controlled clinical trial of long-term antibiotic treatment (1 mo of ceftriaxone followed by 2 mo of doxycycline) of patients with "chronic" Lyme disease was discontinued before full enrollment was reached, concluding that long-term treatment with antibiotics was no more effective than placebo. After reviewing the preliminary data, the data monitoring board concluded that the chance of finding a statistically significant difference in the outcomes of patients in the treatment group vs. the placebo group was virtually nil, even if full enrollment was reached.

Prognosis.

There is a widespread misconception that Lyme disease is difficult to treat successfully and that chronic symptoms and clinical recurrences are common. In fact, the most common reason for apparent treatment failure is misdiagnosis in patients who do not have Lyme disease. The impression that Lyme disease requires prolonged treatment, including intravenous antimicrobial therapy, and that treatment is often unsuccessful can be attributed to the treatment of patients whose symptoms were not due to Lyme disease.

The prognosis for children treated for Lyme disease is excellent. Cases in children treated for erythema migrans rarely progress to late Lyme disease. The long-term prognosis for patients who are treated beginning in the late phase of Lyme disease also is excellent. Although recurrences of arthritis do occur rarely, especially among patients with the DR2, DR3, or DR4 HLA allotypes (an autoimmune process), most children who are treated for Lyme arthritis are permanently cured. Although there are rare reports of adults who have developed late neuroborreliosis after being treated for Lyme disease, no similar cases have been documented in children.

Prevention.

Children in endemic areas are often bitten by deer ticks, but the overall risk of acquiring Lyme disease is low (1–3%), even in these areas. Even if the patient is

bitten by a nymphal stage deer tick infected with *B. burgdorferi*, the risk of acquiring Lyme disease is only 8–10%. If infection develops, treatment of the infection is highly effective. A recent study of prophylaxis among persons 12 yr of age and older found that a single dose of doxycycline (200?mg PO) was 87% effective in preventing Lyme disease (although the lower bound of the 95% confidence interval for this estimate was only 25%). Because most people who recognize a deer tick bite remove the tick within 48 hours (before the tick can transmit Lyme disease), the overall risk of Lyme disease after a recognized bite is low and administration of antimicrobial prophylaxis is not recommended routinely. The routine testing of ticks that have been removed from humans for infection with *B. burgdorferi* also is not recommended because the predictive value of a positive test result (in the tick) for infection in the human host is unknown.

The most reasonable approach to preventing Lyme disease is to wear appropriate protective clothing when entering tick-infested areas and to check for and remove ticks after spending time in such areas. Insect repellents may provide temporary protection, but they may be absorbed from the skin and, if used frequently or in large doses, they may produce significant toxicity, especially in children.

VACCINE.

A Lyme vaccine composed of recombinant OspA protein was shown to be effective and safe, and was licensed in 1998 for persons 15–70 yr of age. Local adverse effects such as pain and swelling at the site of the injection were common. Many experts had reservations about the advisability of routine use of a vaccine for a disease that is relatively rare and that is usually easily treated. These reservations, coupled with the

theoretical concern for potentiation of symptoms of arthritis or Lyme disease in vaccinees, resulted in low demand that led the manufacturer to withdraw the vaccine from the market in early 2002.

Section 7 - *Mycoplasmal Infections*

Dwight A. Powell

Chapter 205 - *Mycoplasma pneumoniae*

Among the five *Mycoplasma* species isolated from the human respiratory tract, *Mycoplasma pneumoniae* is the only recognized human pathogen. It is a major cause of respiratory infections in school-aged children and young adults.

Etiology.

M. pneumoniae, originally thought to be a virus and called the Eaton agent, was found to be a *Mycoplasma* in the early 1960s. Mycoplasmas are the smallest self-replicating biologic system and are dependent on attachment to host cells for obtaining essential precursors such as nucleotides, fatty acids, sterols, and amino acids. They contain double-stranded DNA with genomes ranging from 577–1380 Kb. *M. pneumoniae* is fastidious, and growth in commercially available culture systems is generally too slow to be of practical clinical use.

Epidemiology.

M. pneumoniae infections occur worldwide and throughout the year. In contrast to the acute, short-lived epidemics of some respiratory agents, *M. pneumoniae* infection is endemic in larger communities, with epidemic outbreaks occurring every 4–7 yr. In smaller communities, infections are sporadic with long-lasting and smoldering outbreaks occurring at irregular intervals.

The occurrence of mycoplasmal illness is related, in part, to age and pre-exposure immunity. Overt illness is unusual before 3 yr of age; younger children appear to have frequent mild or subclinical infections, and reinfections appear to be common. The peak incidence of illness occurs in school-aged children; *M. pneumoniae* accounts for 7–30% of all community acquired pneumonias in children 3–15 yr of age. Recurrent infections occur infrequently but are well documented to occur in adults at intervals of 4–7 yr.

High rates of transmission have been documented within families, with a high proportion of secondary cases involving lower respiratory tract infections. Infection occurs through the respiratory route by large droplet spread. The incubation period is thought to be 1–3 wk. Outbreaks can occur in closed settings (e.g., military recruits, institutions, and summer camps for children) or can occur as community epidemics.

Pathogenesis.

Cells of the ciliated respiratory epithelium are the target cells of *M. pneumoniae* infection. The organism is an elongated snakelike structure with an attachment tip characterized by an electron-dense core and a trilaminar outer membrane. Attachment to the ciliary membrane is mediated by a complex network of interactive adhesion and adherence-accessory proteins localized to this specialized attachment tip. These proteins cooperate structurally and functionally to mobilize and concentrate adhesion proteins at the tip and permit mycoplasmal colonization of mucous membranes. Avirulent phenotypes that arise through spontaneous mutations at high frequency cannot synthesize specific cytoadherence-related proteins or are unable to stabilize them at the tip organelle.

Virulent organisms attach to ciliated respiratory epithelial cell surfaces through sialated glycoprotein receptors and burrow down between cells, resulting in ciliastasis and eventual sloughing of the cells. Although the mechanisms of cytopathology have not been determined, intracellular organisms have not been found, and *M. pneumoniae* rarely invades beyond the basement membrane.

Although the presence of circulating antibodies in humans correlates with protection against *M. pneumoniae* infections, studies in the hamster model have shown that circulating antibody alone, in the absence of other forms of immunity, provides incomplete protection. In hamsters, most of the peribronchial mononuclear cells are laden with antibody. However, ablation of the T-cell system with antithymocyte serum completely prevents the development of pneumonia. Thus, the disease produced by *M. pneumoniae* is very complex; the immunologic response of the host may be responsible for the manifestations of disease itself as well as for protection against infection, depending on the qualitative and quantitative balance of humoral and cellular immunity. Patients with immunodeficiency such as hypogammaglobulinemia and sickle cell disease may have more severe mycoplasmal pneumonia than do immunocompetent hosts. *M. pneumoniae* may persist for years in the respiratory tract of patients with hypogammaglobulinemia despite multiple courses of antibiotics. *M. pneumoniae* is one of the most common infectious causes of acute chest syndrome in sickle cell disease, but is not prevalent in patients with AIDS.

Clinical Manifestations.

Bronchopneumonia is the most commonly recognized clinical syndrome associated with *M. pneumoniae* infection. Although the onset of illness may be abrupt, it is usually characterized by gradual onset of headache, malaise, fever, and sore throat, followed by progression of lower respiratory symptoms including hoarseness and cough. Coryza is unusual with *M. pneumoniae* pneumonia and usually suggests a

viral etiology. Although the clinical course in untreated individuals is variable, coughing usually worsens during the first 2 wk of illness, then all symptoms gradually resolve within 3–4 wk. The cough is initially nonproductive, but older children and adolescents may produce a frothy, white sputum. The severity of symptoms is usually greater than that suggested by the physical signs, which appear later in the disease. Crackles or rales, which are fine and resemble those heard in asthma and bronchiolitis, are the most prominent sign. With progression of the disease, the fever intensifies, the cough becomes more troublesome, and the patient may become dyspneic.

Radiographic findings are not specific. Pneumonia is usually described as interstitial or bronchopneumonic; involvement is most common in the lower lobes, with unilateral, centrally dense infiltrates described in 75% of cases. Lobar pneumonia is seen infrequently. Hilar lymphadenopathy may occur in up to 33% of patients. Significant amounts of pleural fluid are unusual, but patients with large effusions due to *M. pneumoniae* have been described as having more severe and prolonged illness compared with those without pleural involvement. The white blood cell and differential counts are usually normal, whereas the erythrocyte sedimentation rate is usually elevated.

Additional respiratory illnesses caused infrequently by *M. pneumoniae* include undifferentiated upper respiratory tract infections, pharyngitis, sinusitis, croup, and bronchiolitis. *M. pneumoniae* is a common trigger of wheezing in asthmatic children. Otitis media and bullous myringitis have been described but are rarely seen without associated lower respiratory tract infection.

Diagnosis.

No specific clinical, epidemiologic, or laboratory observations permit a definite diagnosis of mycoplasmal infection early in the clinical course. Certain observations, however, are suggestive and can be helpful. Pneumonia in school-aged children and young adults, especially if cough is a prominent finding, is always suggestive of *M. pneumoniae* disease. Cultures on special media of the throat or sputum may demonstrate *M. pneumoniae*, but growth is rarely detected earlier than 1 wk, and few commercial laboratories maintain the capability of culturing *M. pneumoniae*. Cold agglutinins are the result of an IgM autoantibody to the I component of the red blood cell surface membrane induced by *M. pneumoniae*. In the presence of cold agglutinins, erythrocytes agglutinate at 4℃ (39.2℉) but not at room temperature. A high titer of cold agglutinins is probably responsible for the hemolytic anemia that sometimes accompanies *M. pneumoniae* infection. A cold agglutinin titer 1:32 or greater suggests *M. pneumoniae* infection. Positive IgM *M. pneumoniae* antibody identified by indirect fluorescence or enzyme-linked immune assay (EIA) more specifically supports the diagnosis. A fourfold increase in IgG *M. pneumoniae* antibody titer, by complement fixation or EIA, between acute and convalescent sera obtained 10 days to 3 wk after the onset of illness is diagnostic. Polymerase chain reaction (PCR) of a nasopharyngeal or throat swab for *M. pneumoniae* DNA has been shown to be rapid, sensitive, and specific in many studies. When *M. pneumoniae* is confirmed in the community in a few patients, the probability of the existence of other mycoplasmal illnesses is greatly increased.

Treatment.

In general, *M. pneumoniae* illness is mild, and hospitalization is infrequently required. Because of the absence of a cell wall, the organism is resistant to the penicillins and cephalosporins. *M. pneumoniae* is exceptionally sensitive to erythromycin, clarithromycin, azithromycin, and the tetracyclines in vitro, which are effective in shortening the course of mycoplasmal illnesses, although they are not mycoplasmacidal. Hence, there may be delay in eradicating the organism from the respiratory tract. Two multicenter studies of pediatric community–acquired pneumonia demonstrated equal efficacy between erythromycin and clarithromycin or azithromycin. These newer macrolides were better tolerated and more effective at eradication of *M. pneumoniae* from the respiratory tract. Clarithromycin (15?mg/kg/24?hr divided bid PO for 10 days) or azithromycin (10?mg/kg PO on day 1 and 5?mg/kg/24?hr PO on days 2–5) eradicated *M. pneumoniae* in 100% of patients studied. Prophylaxis with azithromycin has been shown to substantially reduce the secondary attack rate in institutional outbreaks.

Complications.

Complications, including bacterial superinfection, are unusual. Despite the reportedly rare isolation of *M. pneumoniae* from nonrespiratory sites such as joints, pleural fluid, and cerebrospinal fluid (CSF), the availability of PCR to detect specific segments of *M. pneumoniae* DNA has led to increasing identification of *M. pneumoniae* in nonrespiratory sites, particularly the central nervous system (CNS). Extra-respiratory illness may therefore involve direct invasion with *M. pneumoniae* or may involve autoimmune mechanisms, which is reflected by the frequency with which human antigens cross react with *M. pneumoniae*. Patients with or without respiratory symptoms may manifest illness involving the skin, CNS, blood, heart, gastrointestinal tract, and joints. Skin lesions include a variety of exanthems, most notably maculopapular rashes, erythema multiforme, and the Stevens-Johnson syndrome. Stevens-Johnson syndrome associated with *M. pneumoniae* usually develops 3–21 days after initial respiratory symptoms, lasts less than 14 days, and is rarely associated with severe complications (Figs. 205–1 and 205–2).

Neurologic complications include meningoencephalitis, transverse myelitis, aseptic meningitis, cerebellar ataxia, Bell palsy, deafness, brainstem syndrome, acute demyelinating encephalitis, and Guillain-Barré syndrome. Neurologic complications occur 3–28 days (mean 10 days) after respiratory illness but may not be preceded by respiratory illness in 20% of cases. Encephalitis occurring within 5 days of the onset of prodromal symptoms may be caused by direct *M. pneumoniae* infection of the CNS; encephalitis occurring >7 days after onset of prodromal symptoms is more likely to be auto-immune. *M. pneumoniae* accounts for 1–15% of all forms of childhood encephalitis and most commonly manifests as seizures, impaired consciousness, facial motor deficit, ataxia, or meningeal signs. Concomitant infection with viral agents such as HSV, HHV6, enteroviruses or respiratory viruses may be common. Involvement of the brain stem may result in severe dystonia and movement disorders. The CSF may be normal or have mild mononuclear pleocytosis. Diagnosis is confirmed with positive CSF PCR, positive PCR from a throat swab, or the presence of definitive serum antibody titers. Findings on MRI include focal ischemic changes, ventriculomegaly, diffuse edema, or multifocal white

matter inflammatory lesions consistent with postinfectious demyelinating encephalomyelitis. Neurologic sequelae occur in 20–30% of patients.

Common hematologic complications include mild degrees of hemolysis with positive Coombs test and minor reticulocytosis 2–3 wk after the onset of illness. Severe hemolysis, which is associated with high titers of cold hemagglutinins (=1:512), is rare, as are thrombocytopenia and coagulation defects. Mild hepatitis, pancreatitis, and protein-losing hypertrophic gastropathy are rarely reported gastrointestinal complications. Myocarditis, pericarditis, and a rheumatic fever-like syndrome are uncommon manifestations, but arrhythmias, ST- and T-wave changes, and cardiac dilation with heart failure may accompany *M. pneumoniae* infection in adults more commonly than children. Transient monoarticular arthritis was described in 1% of patients in one large series.

It is unclear from existing literature whether antibiotic treatment of *M. pneumoniae* infection decreases the risk of complications. There is also no specific established therapy for most of the complications. Corticosteroids have been the most frequently used agents in the management of severe *M. pneumoniae* complications, particularly neurologic complications.

Figure 205-1 Lip changes found in Stevens-Johnson syndrome associated with *Mycoplasma pneumoniae* infection.

Figure 205-2 Classic erythema multiforme skin lesions found in Stevens-Johnson syndrome associated with *Mycoplasma pneumoniae* infection.

Prognosis.

Fatal *M. pneumoniae* infections are very rare. Anatomic abnormalities such as altered lung perfusion, mild bronchiectasis, and bronchial wall thickening were detected by high-resolution CT in 37% of children 1–2 yr following *M. pneumoniae* pneumonia. Abnormalities in pulmonary gas diffusion have been reported in nearly half of children 6 mo after recovery from *M. pneumoniae*. Patients generally recover without complications, although sequelae of encephalitis may be severe and permanent.

Chapter 206 - Genital Mycoplasmas (*Mycoplasma hominis and Ureaplasma urealyticum*)

Two *Mycoplasma* species, *Mycoplasma hominis* and *Ureaplasma urealyticum*, are human urogenital pathogens. They are often associated with sexually transmitted diseases such as nongonococcal urethritis (NGU) or puerperal infections such as endometritis. Both organisms commonly colonize the female genital tract and are capable of causing chorioamnionitis, colonization of neonates, and perinatal infections. *M. genitalium* has been implicated as a possible cause of NGU. Two other genital *Mycoplasma* species, *M. fermentans* and *M. penetrans*, have been identified in respiratory or genitourinary secretions with greater frequency in patients infected with HIV than in those without HIV. This has led to speculation, as yet unproven, that these mycoplasmas may play a role as cofactors in progression of HIV infection.

Etiology.

M. hominis and *U. urealyticum* require sterols for growth and can grow in cell-free media. They produce characteristic colonies on agar (*M. hominis*: 200–300?µm, with a "fried-egg" appearance; *U. urealyticum*: 16–60?µm). They are resistant to ß-lactams because they lack a cell wall, and resistant to sulfonamides and trimethoprim because they do not produce folic acid. All seven serovars of *M. hominis* are susceptible to clindamycin, moderately susceptible to chloramphenicol, and resistant to erythromycin and rifampin. Aminoglycosides have limited activity, and increasing numbers of tetracycline-resistant strains are being reported. There are 14 serovars of *U. urealyticum*, and most are susceptible to erythromycin, clarithromycin, and the newer quinolones but resistant to clindamycin. Susceptibility to aminoglycosides and tetracyclines is variable.

Epidemiology.

M. hominis and *U. urealyticum* colonize the genital and urinary tracts of postpubertal females and males. Female colonization is maximal in the vagina and less in the endocervix, urethra, or endometrium. Male colonization occurs primarily in the urethra. Colonization rates are directly related to sexual activity, with colonization occurring in <10% of prepubertal children and sexually inactive adults. Rates are highest in those with multiple sexual partners. Colonization of pregnant females varies from 40–90%, and vertical transmission rates of 25–60% are observed among neonates born to colonized women. Contamination from colonized amniotic fluid or during vaginal delivery is the usual route of neonatal acquisition. However, neonatal colonization can occur in the presence of intact amniotic fluid membranes and with delivery by cesarean section. Colonization rates are highest in infants weighing <1,500?g, in the presence of clinical chorioamnionitis, and among newborns to mothers of lower socioeconomic status. Organisms are recovered from the newborn's throat, vagina, rectum, and, occasionally, eyes for as long as 3 mo after birth.

Pathogenesis.

Genital mycoplasmas can produce chronic inflammation of the genitourinary tract and amniotic fluid membranes. *U. urealyticum* may infect the amniotic sac early in gestation without rupturing the fetal membranes, resulting in a clinically silent, chronic chorioamnionitis characterized by an intense inflammatory response. Attachment to fetal human tracheal epithelium has been shown to cause ciliary disarray, clumping, and loss of epithelial cells. *U. urealyticum* induces macrophages in vitro to increase production of interleukin-6 (IL-6) and tumor necrosis factor 2. Very low birthweight infants colonized with *U. urealyticum* have been shown to have increased levels of monocyte chemoattractant protein and IL-8, which are proinflammatory agents possibly associated with development of bronchopulmonary dysplasia. Immunity appears to require serotype-specific antibody. Thus, a lack of maternal antibody may account for a higher risk of disease in premature newborns.

Clinical Manifestations.

In adults and sexually active adolescents, genital mycoplasmas are associated with sexually transmitted diseases and uncommonly associated with focal infections outside the genital tract. *M. hominis* has been described causing septicemia, wound infection, osteomyelitis, lymphadenitis, meningitis, brain abscess, and arthritis. Life-threatening mediastinitis, sternal wound infections, pleuritis, and pericarditis have been reported with high mortality rates in patients following organ transplant. Extragenital *U. urealyticum* infections are rarely described but include osteomyelitis, arthritis, meningitis, mediastinitis, infection of aortic grafts, and postcesarean wound infections. Patients with hypogammaglobulinemia appear to be at high risk for chronic arthritis caused by various *Mycoplasma*.

U. urealyticum and *M. genitalium* are confirmed pathogens of NGU; approximately 30% of cases in males may be caused by these organisms either alone or together with *Chlamydia trachomatis* (see Chapter 208). Disease is most common in young adults but is also prevalent in sexually active adolescents. The average incubation period is 2–3 wk, with symptoms typically consisting of scanty, mucoid-white urethral discharge, dysuria, and penile discomfort. The discharge is often evident only in the morning or after the urethra is stripped. Rare complications of nongonococcal urethritis are epididymitis and proctitis. Approximately 20–60% of patients with acute NGU will develop recurrent or chronic urethritis despite 1–2 wk of treatment. *U. urealyticum* and *M. genitalium* appear to be the most likely agents of chronic symptomatic urethritis. Females rarely have urethritis and despite high vaginal colonization rates, vaginitis or cervicitis is uncommon. *M. hominis* is an occasional contributing cause of pelvic inflammatory disease, and both genital mycoplasmas are rarely associated with endometritis and postpartum sepsis.

NEONATES.

Genital mycoplasmas are associated with a variety of fetal and neonatal infections. *U. urealyticum* may cause clinically inapparent chorioamnionitis resulting in an eightfold increase in fetal death or premature delivery. Up to 50% of infants <34 wk of gestational age may have *U. urealyticum* recovered from tracheal, blood, cerebrospinal fluid (CSF), or lung biopsy specimens. The role of these organisms causing severe respiratory insufficiency, the need for assisted ventilation, the development of bronchopulmonary dysplasia, or death remains controversial. A large number of controlled studies have investigated this question. Early studies demonstrated that infants weighing <1,000?g who had *U. urealyticum* isolated from tracheal aspirates within the first 24?hr of life were twice as likely to die or develop chronic lung disease compared with uninfected infants of similar birthweight or those weighing >1,000?g. More recent studies, controlling for gestational age and other factors, have shown no correlation between the respiratory isolation of *U. urealyticum* and development of bronchopulmonary dysplasia, duration of ventilatory support, oxygen dependency, or length of hospitalization. Furthermore, a small study of intravenous erythromycin for 1 wk after birth in infants with tracheobronchial colonization of *U. urealyticum* failed to show any difference in treated versus nontreated infants in the development of chronic lung disease. Thus, although it is clear that a high percentage of premature infants are colonized with *U. urealyticum*, the pathogenicity in premature infants awaits further study.

M. hominis and *U. urealyticum* have been isolated from the CSF of premature and, in a few cases, full-term infants. Simultaneous isolation of other pathogens is unusual, and most infants have no overt signs of central nervous system infection. CSF pleocytosis is not a consistent observation, and spontaneous clearance of mycoplasmas has been documented without specific therapy. *U. urealyticum* meningitis has been associated with intraventricular hemorrhage and hydrocephalus; meningitis due to *M. hominis* may be benign. The onset of meningitis varies from 1–196 days of life; organisms may persist in the CSF without therapy for days to weeks. *M. hominis* and *U. urealyticum* have been described to cause neonatal conjunctivitis, lymphadenitis, pharyngitis, pneumonitis, osteomyelitis, and scalp abscess.

Diagnosis.

Diagnosis of a genital tract infection may be difficult because of high colonization rates in the vagina and urethra. Nongonococcal urethritis is confirmed by Gram stain of urethral discharge showing at least three polymorphonuclear leukocytes/oil-immersion field and the absence of gram-negative diplococci. A urethral swab or exudate should be cultured for *C. trachomatis* and *U. urealyticum*.

NEONATES.

U. urealyticum and *M. hominis* have been isolated from urine, blood, CSF, tracheal aspirates, pleural fluid, abscess, and lung tissue. Premature neonates who are clinically ill with pneumonitis, focal abscesses, or central nervous system disease (particularly progressive hydrocephalus with or without pleocytosis) for whom bacterial cultures are negative or in whom there is no improvement with standard antibiotic therapy warrant cultures for genital mycoplasmas. Isolation requires special media, and clinical specimens must be cultured immediately or be frozen at -80°C to avoid loss of organisms. When inoculated into broth containing arginine *(M. hominis)* or urea *(U. urealyticum)*, growth is indicated by an alkaline pH. Identification of *U. urealyticum* on agar requires 1–2 days of growth and visualization with the dissecting microscope, whereas *M. hominis* is apparent to the eye but may require 1 wk to grow. Cultures from the upper respiratory tract are probably meaningless owing to high colonization rates. Cultures of the lower respiratory tract through endotracheal aspirate or biopsy are essential.

Treatment.

Nongonococcal urethritis in adolescents and adults is treated with azithromycin (1?g PO as a single dose) or doxycycline (100?mg bid PO for 7 days). Sexual partners should also be treated to avoid recurrent disease. Nongenital mycoplasmal infections may require surgical drainage and prolonged antibiotic therapy. *M. hominis* is resistant to erythromycin and newer macrolide antibiotics but usually susceptible to clindamycin and variably susceptible to quinolones and tetracycline. *U. urealyticum* are susceptible to tetracycline, aminoglycosides, and quinolones.

NEONATES.

Therapy for neonatal genital mycoplasma infections is indicated in infections associated with a pure growth of the organism and evidence that the disease manifestations are compatible with an infectious process rather than merely colonization. The role of therapy in preventing chronic lung disease in very low birthweight infants awaits results of further studies. Treatment is based on predictable antimicrobial sensitivities because susceptibility testing is not readily available. For symptomatic central nervous system infections, doxycycline is recommended. The long-term consequences of asymptomatic central nervous system infection with genital mycoplasmas, especially in the absence of pleocytosis, are unknown. Because mycoplasmas may spontaneously be cleared from the CSF, therapy should involve minimal risks.

Section 8 - *Chlamydial Infections*

Margaret R. Hammerschlag

Chapter 207 - *Chlamydia pneumoniae*

Chlamydia pneumoniae is increasingly recognized as a common cause of lower respiratory tract diseases, including pneumonia in children and bronchitis and pneumonia in adults. The first isolates of *C. pneumoniae* were obtained during studies of trachoma in the 1960s. Subsequent serologic studies demonstrated that the organism caused an outbreak of mild pneumonia among school children in Finland in 1978. In 1986, the organism was isolated from the respiratory tract of college students with acute respiratory disease.

Etiology.

Chlamydiae are obligate intracellular pathogens that have established a unique niche within the host cell. Chlamydiae cause a variety of diseases in animal species at virtually all phylogenic levels. The order contains one genus, *Chlamydia*, with four recognized species: *C. pneumoniae*, *C. trachomatis, C. psittaci*, and *C. pecorum*. *C. pneumoniae* and *C. trachomatis* are the most significant human pathogens. *C. psittaci* is an important zoonosis. DNA hybridization studies show <5% relatedness between *C. pneumoniae*, *C. trachomatis*, and *C. psittaci*. Recent taxonomic analysis using the 16S and 23S rRNA genes has supported splitting the genus *Chlamydia* into two genera, *Chlamydia* and *Chlamydophila*. *Chlamydia* would contain *C. trachomatis* and two new species, *Chlamydia muridarum* (formerly the agent of mouse pneumonitis, MoPn) and *C. suis*. *Chlamydophila* would contain *C. pecorum, C. pneumoniae*, *C. psittaci*, and three new species split out from *C. psittaci*: *C. abortus*, *C. caviae* (formerly *C. psittaci* guinea pig conjunctivitis strain), and *C. felis*. There is continuing controversy regarding this reclassification.

Chlamydiae are characterized by a unique developmental cycle with morphologically distinct infectious and reproductive forms: **elementary body** (EB) and **reticulate body** (RB). Chlamydiae have a gram-negative envelope without detectable peptidoglycan, although recent genomic analysis has revealed that both *C. pneumonia* and *C. trachomatis* encode proteins forming a nearly complete pathway for synthesis of peptidoglycan, including penicillin-binding proteins. Chlamydiae also share a group-specific lipopolysaccharide antigen and use host adenosine

triphosphate for the synthesis of chlamydial proteins. Although chlamydiae are auxotrophic for 3 of 4 nucleoside triphosphates, they do encode functional glucose-catabolizing enzymes that can be used for generation of ATP. As with peptidoglycan synthesis, for some reason these genes are turned off. All Chlamydiae also encode an abundant protein called the **major outer membrane protein** (MOMP, or OmpA) that is surface exposed in *C. trachomatis* and *C. psittaci*, but apparently not in *C. pneumoniae*. The MOMP is the major determinant of the serologic classification of *C. trachomatis* and *C. psittaci* isolates.

Epidemiology.

C. pneumoniae appears to be a primary human respiratory pathogen. The organism has also been isolated from nonhuman species, including horse, koalas, reptiles, and amphibians, although the role these infections may play in transmission to humans is unknown. *C. pneumoniae* appears to affect individuals of all ages. The proportion of community-acquired pneumonias associated with *C. pneumoniae* infection has ranged from 2–19%, varying with geographic location, the age group examined, and the diagnostic methods used. Several studies of the role of *C. pneumoniae* in lower respiratory tract infection in pediatric populations have found evidence of infection from none to more than 18%. Most of these studies have relied entirely on serology for diagnosis. Results of a large U.S. multicenter study of community-acquired pneumonia in children 3–12 yr of age found evidence of *C. pneumoniae* infection, based on culture, in 14% and of *Mycoplasma pneumoniae* in 22%. The prevalence of *C. pneumoniae* infection in children 6 yr of age or younger was 15%; in those older than 6 yr of age it was 18%. Almost 20% of the children with *C. pneumoniae* infection were co-infected with *M. pneumoniae*. *C. pneumoniae* may also be responsible for 10–20% of episodes of acute chest syndrome in children with sickle cell disease, 10% of episodes of bronchitis, and 5–10% episodes of pharyngitis in children. Transmission probably occurs from person to person through respiratory droplets. Spread of the infection can occur among members in the same household.

Pathogenesis.

Following infection, the infectious EBs, which are 200–400?µm in diameter, attach to the host cell by a process of electrostatic binding and are taken into the cell by endocytosis that does not depend on the microtubule system. Within the host cell, the EB remains within a membrane-lined phagosome. The phagosome does not fuse with the host cell lysosome. The inclusion membrane is devoid of host cell markers, but lipid markers traffic to the inclusion, which suggests a functional interaction with the Golgi apparatus. The EBs then differentiate into RBs that undergo binary fission. After approximately 36?hr, the RBs differentiate into EBs. At about 48?hr, release may occur

by cytolysis or by a process of exocytosis or extrusion of the whole inclusion, leaving the host cell intact. Chlamydiae may also enter a persistent state after treatment with certain cytokines such as interferon-?, treatment with antibiotics, or restriction of certain nutrients. While Chlamydiae are in the persistent state, metabolic activity is reduced. The ability to cause prolonged, often subclinical, infection is one of the major characteristics of Chlamydiae.

Clinical Manifestations.

Infections caused by *C. pneumoniae* cannot be readily differentiated from those caused by other respiratory pathogens, especially *M. pneumoniae*. The pneumonia usually presents as a classic atypical (or nonbacterial) pneumonia characterized by mild to moderate constitutional symptoms including fever, malaise, headache, cough, and frequently pharyngitis. However, severe pneumonia with empyema has been described.

C. pneumoniae may serve as an infectious trigger for asthma and can cause pulmonary exacerbations in patients with cystic fibrosis. *C. pneumoniae* has been isolated from middle ear aspirates of children with acute otitis media, but is usually associated with bacterial otitis media. Asymptomatic respiratory infection has been documented in 2–5% of adults and children and may persist for a year or more.

Diagnosis.

It is not possible to differentiate *C. pneumoniae* from other causes of atypical pneumonia on the basis of clinical findings. Auscultation reveals the presence of rales and often wheezing. The chest radiograph often appears worse than the patient's clinical status would indicate and may show mild, diffuse involvement or lobar infiltrates with small pleural effusions. The complete blood count may be elevated with a left shift but is usually unremarkable.

Specific diagnosis of *C. pneumoniae* infection is based on isolation of the organism in tissue culture. *C. pneumoniae* grows best in cycloheximide-treated HEp-2 and HL cells. The optimum site for culture is the posterior nasopharynx; the specimen is collected with wire-shafted swabs in the same manner as that used for *C. trachomatis*. The organism can be isolated from sputum, throat cultures, bronchoalveolar lavage fluid, and pleural fluid, but few laboratories perform such cultures because of technical difficulties.

Polymerase chain reaction (PCR) testing appears to be the most promising technology in the development of a rapid, nonculture method for detection of *C. pneumoniae*. Numerous PCR assays for detection of *C. pneumoniae* in clinical specimens have been reported but none of these assays are standardized or have been extensively validated compared with culture for detection of *C. pneumoniae* in respiratory specimens. None are commercially available or have Food and Drug Administration approval.

Serologic diagnosis can be accomplished using the microimmunofluorescence (MIF) or the complement fixation (CF) tests. The CF test is genus specific and is also used for diagnosis of lymphogranuloma venereum (Chapter 208.4) and psittacosis (Chapter 209). Its sensitivity in hospitalized patients with *C. pneumoniae* infection and children is variable. The Centers for Disease Control and Prevention (CDC) recently proposed modifications in the serologic criteria for diagnosis. Although the MIF test was considered to be the only currently acceptable serologic test, the criteria were made significantly more stringent. Acute infection, using the MIF test, was defined by a fourfold increase in IgG titer or an IgM titer of 16 or greater; use of

a single elevated IgG titer was discouraged. An IgG titer of 16 or greater was thought to indicate past exposure, but neither elevated IgA titers nor any other serologic marker was thought to be a valid indicator of persistent or chronic infection. The CDC did not recommend the use of any enzyme-linked immune assay (EIA) test for detection of antibody to *C. pneumoniae* because there is concern about the inconsistent correlation of these results with culture results. Studies of *C. pneumoniae* infection in children with pneumonia and asthma show that more than 50% of children with culture-documented infection have no detectable MIF antibody.

Treatment.

The optimum dose and duration of antimicrobial therapy for *C. pneumoniae* infections remain uncertain. Most treatment studies have used serology only for diagnosis, thus the microbiologic efficacy cannot be assessed. Prolonged therapy (=2 wk) may be desirable because recrudescent symptoms and persistent positive cultures have been described following 2 wk of erythromycin and 30 days of tetracycline or doxycycline.

Tetracyclines, erythromycin, the newer macrolides (azithromycin and clarithromycin), and quinolones show in vitro activity. Like *C. psittaci*, *C. pneumoniae* is resistant to sulfonamides. The results of recent treatment studies have shown that erythromycin (40?mg/kg/24?hr divided bid PO for 10 days), clarithromycin (15?mg/kg/24?hr divided bid PO for 10 days), and azithromycin (10?mg/kg/24 PO on day 1, 5?mg/kg/24?hr PO on days 2–5) are effective for eradication of *C. pneumoniae* from the nasopharynx of children with pneumonia in approximately 80% of cases.

Prognosis.

Clinical response to antibiotic therapy varies. Coughing often persists for several weeks even after therapy.

Chapter 208 - *Chlamydia trachomatis*

The organism *Chlamydia trachomatis* is subdivided into two biovars: lymphogranuloma venereum (LGV) and trachoma (the agent of human oculogenital diseases other than LGV). Although the strains of both biovars have almost complete DNA homology, they differ in growth characteristics and virulence in tissue culture and animals. In developed countries, *C. trachomatis* is the most prevalent sexually transmitted disease, causing urethritis in men, cervicitis and salpingitis in women, and conjunctivitis and pneumonia in infants.

208.1 Trachoma

Trachoma is the most important preventable cause of blindness in the world. It is caused primarily by the A, B, Ba, and C serotypes of *C. trachomatis*. It is endemic in the Middle East and Southeast Asia and among Navajo Indians in the southwestern United States. In areas that are endemic for trachoma, such as Egypt, genital chlamydial infection is caused by the serotypes responsible for oculogenital disease: D, E, F, G, H, I, J, and K. The disease is spread from eye to eye. Flies are a frequent vector.

Trachoma begins as a follicular conjunctivitis, usually in early childhood. The follicles heal, leading to conjunctival scarring that may result in an entropion, with the eyelid turning inward so that the lashes abrade the cornea. It is the corneal ulceration secondary to the constant trauma that leads to scarring and blindness. Bacterial superinfection may also contribute to scarring. Blindness occurs years after the active disease.

Trachoma can be diagnosed clinically. The World Health Organization suggests that at least two of four criteria must be present for a diagnosis of trachoma: (1) lymphoid follicles on the upper tarsal conjunctivae, (2) typical conjunctival scarring, (3) vascular pannus, and (4) limbal follicles. The diagnosis is confirmed by culture or staining tests for *C. trachomatis* performed during the active stage of disease. Serologic tests are not helpful clinically because of the long duration of the disease and the high seroprevalence in endemic populations.

Poverty and lack of sanitation are important factors in the spread of trachoma. As socioeconomic conditions improve, the incidence of the disease decreases substantially. Endemic trachoma has been controlled in most instances by administering topical tetracyclines (or, rarely, erythromycin ointment) daily for periods of 6–10 wk or intermittently over a 6-mo period. Oral doxycycline is effective but is contraindicated in children younger than 9 yr of age. Oral erythromycin requires frequent dosing, which is impractical in the control of endemic trachoma. A recent study reported that 1–6 doses of oral azithromycin was equivalent to 30 days of treatment with topical oxytetracycline/polymyxin ointment. Currently the WHO recommends single-dose azithromycin (20?mg/kg; maximum: 1?g) for the treatment of trachoma in children.

208.2 Genital Tract Infections

Epidemiology.

There are an estimated 3 million new cases of chlamydial sexually transmitted infections each year in the United States. *C. trachomatis* is a major cause of epididymitis and is the cause of 23–55% of all cases of nongonococcal urethritis, although the proportion of chlamydial nongonococcal urethritis has been gradually declining. As many as 50% of men with gonorrhea may be co-infected with *C. trachomatis*. The prevalence of chlamydial cervicitis among sexually active women is 2–35%. Rates of infection among adolescent girls exceed 20% in many urban populations but can be as high as 15% in suburban populations as well (Chapter 110).

Children who have been sexually abused may acquire anogenital *C. trachomatis* infection, which is usually asymptomatic. Culture is the only method that should be used for diagnosis of *C. trachomatis* from these sites when a prepubertal child is being tested for suspected sexual abuse. However, because perinatally acquired rectal and vaginal *C. trachomatis* infections may persist for =3 yr, the detection of *C. trachomatis* in the vagina or rectum of a young child is not absolute evidence of sexual abuse.

Clinical Manifestations.

The trachoma biovar of *C. trachomatis* causes a spectrum of disease in sexually active adolescents and adults. Up to 75% of women with *C. trachomatis* have no symptoms of infection. *C. trachomatis* can cause urethritis (acute urethral syndrome), epididymitis, cervicitis, salpingitis, proctitis, and pelvic inflammatory disease. The symptoms of chlamydial genital tract infections are less acute than those of gonorrhea, consisting of a discharge that is usually mucoid rather than purulent. Asymptomatic urethral infection is frequent in sexually active men. Autoinoculation from the genital tract to the eyes can lead to concomitant inclusion conjunctivitis.

Diagnosis.

Definitive diagnosis of genital chlamydial infection is accomplished by isolation of the organism in tissue culture and confirmed by microscopic identification of the characteristic inclusions using fluorescent antibody staining in culture specimens obtained from the urethra in men and the endocervix in women. Care should be taken to obtain epithelial cells, not only discharge. *C. trachomatis* can be cultured in cycloheximide-treated HeLa, McCoy, and HEp-2 cells. *Chlamydia* culture has been

further defined by the CDC as isolation of the organism in tissue culture and as confirmation of the characteristic intracytoplasmic inclusions by fluorescent antibody staining.

Alternatively, a nonculture method, specifically a nucleic acid amplification test (NAAT) can be used. These tests have high sensitivity, perhaps even detecting 10–20% greater than culture, while retaining high specificity. There are currently four Food and Drug Administration (FDA)-approved, commercially available NAATs for *Chlamydia* using different methods: polymerase chain reaction (PCR) (Amplicor *Chlamydia* test, Roche Molecular Diagnostics, Nutley, NJ); ligase chain reaction (LCR) (LCx *Chlamydia trachomatis* assay, Abbott Diagnostics, Abbott Park, IL); strand displacement amplification (SDA) (BeAware GC/CT, BD Diagnostic Systems, Sparks, MD); and transcription mediated amplification (TMA) (Amp CT, Gen-Probe, San Diego, CA). PCR, LCR, and SDA are all DNA amplification tests that use primers that target gene sequences on the cryptogenic *C. trachomatis* plasmid, which is present at approximately 10 copies/cell. TMA is an rRNA amplification assay. The SDA test and a version of the TMA test (PACE, Gen-Probe) are a dual assay for simultaneously detecting *C. trachomatis* and *Neisseria gonorrhoeae*. Currently available commercial NAATs have FDA approval for cervical swabs from women, urethral swabs from men, and urine from men and women. The use of urine avoids the necessity for a clinical pelvic examination and may greatly facilitate screening in certain populations, especially adolescents. Data on use of NAATs for vaginal specimens or urine from children are very limited and insufficient to allow making a recommendation for their use. The CDC recommends that NAATs may be used as an alternative to culture *only* if confirmation is available. Confirmation tests should consist of a second FDA-approved NAAT that targets a different gene sequence from the initial test.

The etiology of most cases of nonchlamydial nongonococcal urethritis is unknown; *Ureaplasma urealyticum* and possibly *Mycoplasma genitalium* are implicated in up to one third of cases (see Chapter 206). Proctocolitis may develop in individuals who have a rectal infection with an LGV strain (see Subchapter 208.4).

Treatment.

Recommended treatment regimens for uncomplicated *C. trachomatis* genital infection in men and nonpregnant women are azithromycin (1?g orally PO as a single dose) or doxycycline (100?mg PO bid for 7 days). Neither of these regimens can be used in pregnant women. Alternative regimens are erythromycin base (500?mg PO qid for 7 days), erythromycin ethylsuccinate (800?mg PO qid for 7 days), ofloxacin (300?mg PO bid for 7 days), and levofloxacin (500?mg PO once daily for 7 days). The high erythromycin dosages may not be well tolerated. Doxycycline and ofloxacin are contraindicated in pregnant women; quinolones are contraindicated in persons younger than 18 yr of age. For pregnant women, the recommended treatment regimen is erythromycin base (500?mg PO bid for 7 days) or amoxicillin (500?mg PO tid for 7 days). Alternative regimens are erythromycin base (250?mg PO qid for 14 days), erythromycin ethylsuccinate (800?mg PO qid for 7 days or 400?mg PO qid for 14 days), and azithromycin (1?g orally in a single dose). Amoxicillin at this dosage is as effective as any of the erythromycin regimens and is much better tolerated. However, experience with all these regimens is still limited.

Empirical treatment without microbiologic diagnosis is recommended only for patients at high risk for infection who are unlikely to return for follow-up evaluation, which includes adolescents with multiple sexual partners. These patients should be treated empirically for both *C. trachomatis* and gonorrhea (Chapter 177).

Sex partners of patients with nongonococcal urethritis should be treated if they have had sexual contact with the patient during the 60 days preceding the onset of symptoms. The most recent sexual partner should be treated even if the last sexual contact was more than 60 days from onset of symptoms.

Complications.

Complications of genital chlamydial infections in women include perihepatitis (Fitz-Hugh-Curtis syndrome) and salpingitis. Of women with untreated chlamydial infection who develop pelvic inflammatory disease, up to 40% will have significant sequelae; approximately 17% will suffer from chronic pelvic pain, approximately 17% will become infertile, and approximately 9% will have an ectopic (tubal) pregnancy. Adolescent girls may be at higher risk for developing complications, especially salpingitis, than older women. Salpingitis in adolescent girls is also more likely to lead to tubal scarring, subsequent obstruction with secondary infertility, and increased risk of ectopic pregnancy. Approximately 50% of neonates born to pregnant women with chlamydial infection will acquire *C. trachomatis* infection (Chapter 208.3). Women with *C. trachomatis* infection have a threefold to fivefold increased risk of acquiring HIV infection.

Prevention.

Timely treatment of sex partners is essential for decreasing risk of re-infection. Sex partners should be evaluated and treated if they had sexual contact during the 60 days preceding onset of symptoms in the patient. The most recent sex partner should be treated even if the last sexual contact was >60 days. Patients and their sex partners should abstain from sexual intercourse until 7 days after a single-dose regimen or after completion of a 7-day regimen.

Annual routine screening for *C. trachomatis* is recommended for all sexually active adolescents and females 20–25 yr of age, and older women with risk factors such as new or multiple partners or inconsistent use of barrier contraceptives. Sexual risk assessment may indicate more frequent screening of some women.

208.3 Conjunctivitis and Pneumonia in Newborns

Epidemiology.

Chlamydial genital infection is reported in 5–30% of pregnant women with a risk of vertical transmission at parturition to newborn infants of about 50%. The infant may

become infected at one or more sites including the conjunctivae, nasopharynx, rectum, and vagina. Transmission is rare following cesarean section with intact membranes.

Clinical Manifestations.

Approximately 70% of infected infants are infected in the nasopharynx. Clinically, the infant may develop conjunctivitis or pneumonia.

INCLUSION CONJUNCTIVITIS.

C. trachomatis is the most frequent identifiable infectious cause of neonatal conjunctivitis, the primary clinical manifestation of neonatal chlamydial infection. Approximately 30–50% of infants born to mothers with active chlamydial infection develop clinical conjunctivitis. Symptoms usually develop 5–14 days after delivery, or earlier with prolonged rupture of membranes. The presentation is extremely variable and ranges from mild conjunctival injection with scant mucoid discharge to severe conjunctivitis with copious purulent discharge, chemosis, and pseudomembrane formation. The conjunctiva may be very friable and may bleed when stroked with a swab. Chlamydial conjunctivitis must be differentiated from gonococcal ophthalmia, which is sight-threatening. At least 50% of infants with chlamydial conjunctivitis also have nasopharyngeal infection.

PNEUMONIA.

Pneumonia due to *C. trachomatis* develops in 10–20% of infants born to women with chlamydial infection. Only about 25% of infants with nasopharyngeal chlamydial infection develop pneumonia. *C. trachomatis* pneumonia of infancy has a very characteristic presentation. Onset is usually between 1 and 3 mo of age and is often insidious with persistent cough, tachypnea, and absence of fever. Auscultation reveals rales; wheezing is uncommon. The absence of fever and wheezing helps to distinguish *C. trachomatis* pneumonia from respiratory syncytial virus (RSV) pneumonia. A distinctive laboratory finding is the presence of peripheral eosinophilia (>400 cells/mm^3). The most consistent finding on chest radiograph is hyperinflation accompanied by minimal interstitial or alveolar infiltrates.

INFECTIONS AT OTHER SITES.

Infants born to mothers with *C. trachomatis* may develop an infection in the rectum or vagina. Although infection in these sites appears to be totally asymptomatic, it may cause confusion if it is identified at a later date. Perinatally acquired rectal, vaginal, and nasopharyngeal infections may persist for =3 yr. *C. pneumoniae* can also be confused with *C. trachomatis* infection in nasopharyngeal cultures if a genus-specific monoclonal antibody is used to confirm the culture.

DIAGNOSIS.

Definitive diagnosis is achieved by isolation of *C. trachomatis* in cultures of specimens obtained from the conjunctiva or nasopharynx. Several nonculture methods, using DFA and EIA, are approved for diagnosis of chlamydial conjunctivitis. These tests have sensitivities of =90% and specificities of =95% for conjunctival specimens compared with culture. Their accuracy for nasopharyngeal specimens is not as good. Data on use of NAATs in children are limited. Preliminary data suggest that PCR is equivalent to culture for detection of *C. trachomatis* in the conjunctiva and nasopharynx of infants with conjunctivitis.

Nonculture methods should never be used to test rectal or vaginal specimens obtained from children. Because all available EIA tests use genus-specific antibodies, these tests also detect *C. pneumoniae* if used for tests of respiratory specimens.

Treatment.

The recommended treatment regimen for *C. trachomatis* conjunctivitis or pneumonia in infants is erythromycin (base or ethylsuccinate, 50?mg/kg/24?hr divided qid PO for 14 days). The rationale for using oral therapy for conjunctivitis is that 50% or more of these infants have concomitant nasopharyngeal infection or disease at other sites, and studies have demonstrated that topical therapy with sulfonamide drops and erythromycin ointment is not effective. The failure rate with oral erythromycin remains 10–20%, and some infants require a second course of treatment. The results of one small study suggest that a short course of azithromycin (20?mg/kg/24?hr once daily PO for 3 days) was as effective as 14 days of erythromycin. Mothers (and their sexual contacts) of infants with *C. trachomatis* infections should be empirically treated for genital infection. An association between treatment with oral erythromycin and infantile hypertrophic pyloric stenosis has been reported in infants younger than 6 wk of age who were given the drug for prophylaxis after nursery exposure to pertussis. Data on use of other macrolides (azithromycin or clarithromycin) for the treatment of neonatal chlamydia infection are limited.

Prevention.

Neonatal gonococcal prophylaxis with topical erythromycin or tetracycline ointment, unlike silver nitrate, does not appear to prevent chlamydial ophthalmia. Neither agent prevents nasopharyngeal colonization with *C. trachomatis* or chlamydial pneumonia. The most effective method of controlling perinatal chlamydial infection appears to be screening and treatment of pregnant women. For treatment of *C. trachomatis* infection in pregnant women, the CDC currently recommends either erythromycin base (500?mg PO qid for 7 days) or amoxicillin (500?mg PO tid for 7 days) as first line regimens. Erythromycin base (250?mg PO qid for 14 days), erythromycin ethylsuccinate (800?mg qid for 7 days, or 400?mg PO qid for 14 days), and azithromycin (1?g PO as a single dose) are listed as alternative regimens. Reasons for failure of maternal treatment to prevent infantile chlamydial infection include poor compliance and reinfection from an untreated sexual partner.

208.4 Lymphogranuloma Venereum (LGV)

LGV is a systemic sexually transmitted disease caused by the L_1 , L_2 , and L_3

serotypes of the LGV biovar of *C. trachomatis*. Unlike strains of the trachoma biovar, LGV strains have a predilection for lymphoid tissue. About 20 cases of LGV have been reported in children, and fewer than 1,000 cases are reported in adults in the United States each year.

Clinical Manifestations.

The first stage of LGV is characterized by the appearance of the primary lesion, a painless, usually transient papule on the genitals. The second stage is characterized by usually unilaterally femoral or inguinal lymphadenitis with enlarging, painful buboes. The nodes may break down and drain, especially in males. In females, the vulvar lymph drains to the retroperitoneal nodes. Fever, myalgia, and headache are common. In the tertiary stage, a genitoanorectal syndrome occurs, with rectovaginal fistulas, rectal strictures, and urethral destruction.

Diagnosis.

LGV is diagnosed by culture of *C. trachomatis* from a specimen aspirated from a bubo or by serologic testing. Most patients with LGV have complement-fixing antibody titers of >1:16. Chancroid and herpes simplex virus can be distinguished clinically from LGV by the concurrent presence of painful genital ulcers. Syphilis can be differentiated by serologic tests. However, co-infections can occur.

Treatment.

Doxycycline (100?mg PO bid for 21 days) is the recommended treatment. The alternative regimen is erythromycin base (500?mg PO qid for 21 days). Azithromycin (1?g PO once weekly for 3 weeks) may also be effective but clinical data are lacking. Sex partners of patients with LGV should be treated if they have had sexual contact with the patient during the 30 days preceding the onset of symptoms.

Chapter 209 - Psittacosis (*Chlamydia psittaci*)

Chlamydia psittaci, the cause of psittacosis (also known as **parrot fever** and **ornithosis**), is primarily an animal pathogen and causes human disease infrequently. In birds, *C. psittaci* infection is known as **avian chlamydiosis**.

Etiology.

C. psittaci is a diverse species that affects nonpsittacine birds and many mammalian species as well. The known host range includes 15 mammalian species and 130 avian species representing 10 orders. The life cycle of *C. psittaci* is the same as that for *C. pneumoniae* (Chapter 207). The diversity of *C. psittaci* probably is a reflection of its wide host range; recent genomic analysis has suggested reorganizing the organism into four separate species in a new genus, *Chlamydophila*. Strains of *C. psittaci* have been analyzed by patterns of pathogenicity, inclusion morphology in tissue culture, DNA restriction endonuclease analysis, and monoclonal antibodies, which indicate that there are nine mammalian serovars, seven avian serovars, and two koala biovars. The mammalian strains differ greatly from avian strains in their antigenic characteristics. Two of the avian serovars, psittacine and turkey, are of major importance in the avian population of the United States. Each is associated with important host preferences and disease characteristics.

Epidemiology.

From 1988 to 1998 there were 813 cases of psittacosis reported in the United States, and 85% of cases were associated with exposure to birds; 70% of these reported cases were the result of exposure to caged pet birds, which were usually psittacine birds including cockatiels, parakeets, parrots, and macaws. Among caged nonpsittacine birds, chlamydiosis occurs most frequently in pigeons, doves, and mynah birds. Persons at highest risk of acquiring psittacosis include bird fanciers and owners of pet birds (43% of cases) and pet shop employees (10% of cases).

Inhalation of aerosols from feces, fecal dust, and secretions of animals infected with *C. psittaci* is the primary route of infection. Source birds are either asymptomatic or have anorexia, ruffled feathers, lethargy, and watery green droppings. Psittacosis is uncommon in children, in part because children may be less likely to have close contact with infected birds. Several major outbreaks of psittacosis have occurred in turkey processing plants; workers exposed to turkey viscera are at the highest risk of infection.

Clinical Manifestations.

Infection with *C. psittaci* in humans ranges from clinically inapparent to severe infection involving multiple organ systems as well as pneumonia. The mean incubation period is 15 days after exposure, with a range of 5–21 days. Onset of disease is usually abrupt with fever, cough, headache, and malaise. The fever is high and often is associated with rigors and sweats. The headache can be so severe that meningitis is considered. The cough is usually nonproductive. Crackles may be heard on auscultation. Chest radiographs are usually abnormal with variable infiltrates, and pleural effusions may be present. The white blood cell count is usually not elevated, but a mild leukocytosis may be present. Elevated levels of aspartate aminotransferase, alkaline phosphatase, and bilirubin are common.

Diagnosis.

The diagnosis of psittacosis can be difficult because of the varying clinical presentations. A history of exposure to birds or association with an active case are important clues, but as many as 20% of patients with psittacosis have no known contact. Person-to-person spread has been suggested but not proved. Other infections that cause pneumonia with high fever, unusually severe headache, and myalgia include *Coxiella burnetii* (Q fever), *Mycoplasma pneumoniae, Chlamydia pneumoniae*, tularemia, tuberculosis, fungal infections, legionnaires' disease, and, most commonly, bacterial and viral respiratory infections.

The mainstay of diagnosis remains serology using the complement-fixation (CF) test, which is genus-specific. According to the 2000 recommendations from the Centers for Disease Control and Prevention, a confirmed case of psittacosis requires a compatible clinical illness, usually with a reliable history of avian exposure. Laboratory confirmation may be by one of the three following methods: (1) culture of *C. psittaci* from respiratory

secretions; (2) a fourfold or greater increase in CF or microimmunofluorescence (MIF) titer in sera collected at least 2 wk apart; or (3) a single MIF IgM titer greater than or equal to 1:16. A probable case should be epidemiologically linked to a confirmed case or have a single CF or MIF antibody titer of 1:32 or more in at least one serum sample obtained after onset of symptoms. As with use of the MIF for diagnosis of *C. pneumoniae* infections, cross reactions with other *Chlamydia* species and bacteria can occur. Early treatment of psittacosis with tetracycline may abrogate the antibody response.

The organism can be also isolated by culture from sputum or pleural fluid. Although *C. psittaci* will grow in the same culture systems used for isolation of *C. trachomatis* and *C. pneumoniae*, very few laboratories culture for *C. psittaci*, mainly because of the potential biohazard.

Treatment.

Recommended treatment regimens for psittacosis are doxycycline (100?mg PO bid) or tetracycline (500?mg PO qid) for at least 10–14 days after the fever abates. The initial treatment of severely ill patients is doxycycline hyclate (4.4?mg/kg/24?hr divided q 12?hr IV; maximum: 100?mg/dose). Erythromycin (500?mg qid PO) is an alternative drug if tetracyclines are contraindicated (e.g., children younger than 9 yr of age and pregnant women), but may be less effective. Remission is usually evident within 48–72 hours. Initial infection does not appear to be followed by long-term immunity. Reinfection and clinical disease can develop within 2 mo of treatment; there are two well-documented cases of reinfection reported.

Prognosis.

The mortality of untreated psittacosis is 15–20%, but is <1% with appropriate treatment. Severe illness leading to respiratory failure and fetal death has been reported among pregnant women.

Prevention.

Several control measures are recommended to prevent transmission of *C. psittaci* from birds. Bird handlers and avatars should be cognizant of the potential risk. *C. psittaci* is susceptible to most disinfectants and detergents as well as heat, but is resistant to acid and alkali. Accurate records of all bird-related transactions aid in identifying sources of infected birds and potentially exposed persons. Newly acquired birds, including birds that have been to shows, exhibitions, fairs, or other events, should be isolated for 30–45 days, or tested or treated prophylactically before adding them to a group of birds. Care should be taken to prevent transfer of fecal material, feathers, food, or other materials between birdcages. Birds with signs of avian chlamydiosis (e.g., ocular or nasal discharge, watery green droppings, or low body weight) should be isolated and should neither be sold nor purchased. Their handlers should wear protective clothing and a disposable surgical cap and use a respirator with an N95 or higher-efficiency rating (not a surgical mask) when handling them or cleaning their cages. Infected birds should be isolated until fully treated, which is generally 45 days.

Chapter 210 - Spotted Fever Group Rickettsioses

Many members of the spotted fever group of rickettsiae are pathogenic for humans (Table 210–1). These include the tick-borne agents *Rickettsia rickettsii* (Rocky Mountain spotted fever [RMSF]), *R. conorii* (Mediterranean spotted fever [MSF] or boutonneuse fever), *R. sibirica* (North Asian tick typhus), *R. japonica* (Oriental spotted fever), *R. australis* (Queensland tick typhus), *R. honei* (Flinders Island spotted fever), *R. africae* (African tick bite fever), the unnamed Israeli spotted fever rickettsia, and possibly others. *R. akari* (rickettsialpox) is transmitted by the bite of a mite. Infections with the uncommon members of the spotted fever group rickettsiae present with signs similar to MSF (fever, maculopapular rash, and eschar at the initial site of tick attachment). Israeli spotted fever is generally associated with a more severe course, including fatalities in children. African tick typhus (*R. africae*) is relatively mild, often lacks disseminated rash, and usually presents with multiple eschars. In recent years, new rickettsial agents have been identified as potentially important pathogenic species, including *R. slovaca*, the cause of TIBOLA (tick-borne lymphadenopathy), and *R. felis*, a flea-transmitted murine typhus-like illness.

210.1 Rocky Mountain Spotted Fever (*Rickettsia rickettsii*)

RMSF is the most frequently identified rickettsial disease and the second most common vector-borne disease in the United States. RMSF is considered uncommon, but it is probably significantly underdiagnosed. Because it is a potentially rapidly fatal infection, RMSF should be considered in the differential diagnosis of fever, headache, and rash in the summer months, especially after tick exposure.

Etiology.

RMSF is caused by systemic endothelial cell infection by the obligate intracellular bacterium *R. rickettsii*.

Epidemiology.

The term *Rocky Mountain* spotted fever is a misnomer because only a small percentage of all documented cases are currently reported from the Rocky Mountain region. The disease occurs in almost every state of the continental United States, southwestern Canada, Mexico, Central America, and

TABLE 210.1-1 -- **Rickettsial Diseases of Humans: Selected Agents and Summary of Pertine Features**

Group Disease	Causative Agent	Arthropod Vector-Transmission	Hosts	Confirmatory Tests
Spotted Fever				
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Tick bite	Dogs, rodents	IFA, DFA, IH
Mediterranean spotted fever (Boutonneuse fever)	*Rickettsia conorii*	Tick bite	Dogs, rodents	IFA, DFA, IH
African tick-bite fever	*Rickettsia africae*	Tick bite	Cattle, goats?	IFA, DFA, IH
Rickettsialpox	*Rickettsia akari*	Mite bite	Mice	IFA, DFA, IH
Murine typhus-like illness	*Rickettsia felis*	Flea bite	Opossums, cats, dogs	IFA, PCR
Typhus				
Murine typhus	*Rickettsia typhi*	Rat flea or cat flea feces	Rats	IFA, DFA
Epidemic typhus	*Rickettsia prowazekii*	Louse feces	Humans	IFA

Brill-Zinsser disease (recrudescent typhus)	*Rickettsia prowazekii*	Reactivation of latent infection	Humans	IFA
Flying squirrel (sylvatic) typhus	*Rickettsia prowazekii*	Louse or flea of flying squirrel	Flying squirrels	IFA
Scrub Typhus				
Scrub typhus	*Orientia tsutsugamushi*	Chigger bite	Rodents?	IFA
Ehrlichioses and Anaplasmosis				
Human monocytic ehrlichiosis	*Ehrlichia chaffeensis*	Tick bite	Deer, dogs	IFA, PCR
Anaplasmosis (human granulocytic ehrlichiosis)	*Anaplasma phagocytophilum*	Tick bite	Rodents, deer, ruminants	IFA, PCR
Ehrlichiosis "ewingii"	*Ehrlichia ewingii*	Tick bite	Dogs	IFA, PCR
Sennetsu ehrlichiosis	*Neorickettsia sennetsu*	Ingestion of helminth-contaminated fish?	Unknown	IFA
Q fever				
Q fever	*Coxiella burnetii*	Inhalation of infected aerosols, ingestion of contaminated dairy products, ticks?	Cattle, sheep, goats, cats, rabbits	IFA

South America. In 1999, most cases were reported from North Carolina, Tennessee, South Carolina, Georgia, Maryland, Oklahoma, Arkansas, and Virginia; however, the changing ecology of tick vectors influences the geographic prevalence over time. The incidence of RMSF varies in a cyclical pattern over decades, the last peak occurring approximately in 1981; since 1996, the average annual number of cases reported to the Centers for Disease Control and Prevention (CDC) has fluctuated around 500 cases/yr. Habitat associations with disease are predicted by those favored by tick vectors including wooded areas or coastal grassland and salt marshes. Foci of intense infection have also been well documented in rural and some urban settings such as the South Bronx, and local abundance of infected ticks may predispose to clusters of cases even in single families. In the United States, 90% of cases occur during seasons of peak tick activity and potential human exposure, between April and September. The highest age-specific incidence of RMSF is among children <10 yr of age.

TRANSMISSION.

Ticks are the natural hosts, reservoirs, and vectors of *R. rickettsii*. Ticks maintain the infection naturally by **transovarial transmission** (passage of the organism from infected ticks to their progeny) with a high rate of fecundity; thus, horizontal transmission by acquisition of rickettsiae when a blood meal is taken from transiently rickettsemic animal hosts such as small mammals or dogs is a significant mechanism for enzootic maintenance of infection. Many species of ticks are capable of sustaining and transmitting the infectious agent to mammalian hosts by regurgitation of infected saliva during feeding. The principal tick hosts of *R. rickettsii* are *Dermacentor variabilis* (the American dog tick) in the eastern United States and Canada, *D. andersoni* (the wood tick) in the western United States and Canada, *Rhipicephalus sanguineus* (the brown dog tick) in Mexico, and *Amblyomma cajennense* in Central and South America.

Dogs may also serve as reservoir hosts for *R. rickettsii* and are important vehicles for bringing potentially infected ticks into the environment shared by humans. Serologic studies of patients with RMSF indicate that a high percentage may have contracted the illness from ticks carried by the family dog. Infection is largely transmitted by way of the bite of an infected tick; however, transmission can occur by inoculation of tick fluids or feces into open wounds or conjunctivae from the fingers and hands. Fatalities have occurred in laboratory workers exposed to infectious aerosols.

Pathogenesis.

Lesions are most obvious on the skin, but are systemically distributed, affecting nearly all organs and tissues. Following inoculation into the dermis, the rickettsiae attach to the vascular endothelium via protein ligands and initiate host cell membrane injury due to rickettsial phospholipase activity. The membrane damage induces phagocytosis and the internalized rickettsia then gains access to the cytosol by continued vacuolar membrane lysis. Members of the spotted fever serologic group actively initiate intracellular actin polymerization to achieve directional movement, and rickettsiae can thus easily invade neighboring cells while inducing minimal initial host cell damage. The rickettsiae proliferate and damage the host cell by peroxidative membrane alterations, protease activation, or continued phospholipase activity.

Initially, a perivascular infiltrate of lymphoid and histiocytic cells and edema without significant endothelial damage is present, coinciding with the development of macules and maculopapules. Proliferation of rickettsiae within endothelial cell cytoplasm leads to lymphohistiocytic or leukocytoclastic vasculitis of small venules and capillaries that results in the formation of petechial skin lesions and microvascular leakage, tissue hypoperfusion, and end-organ ischemic injury. Rickettsiae are localized within endothelial cells of inflamed vessels that may be

eccentrically involved, including infrequent nonocclusive thrombi; small and large vessels rarely become completely obliterated by thrombosis, leading to tissue infarction or hemorrhagic necrosis. Sequelae result from interstitial pneumonitis and vascular leakage in the lungs, leading to noncardiogenic pulmonary edema, or from meningoencephalitis, leading to cerebral edema.

The presence of the infectious agent initiates the inflammatory cascade including release of cytokines such as tumor necrosis factor-a (TNFa), interleukin-1ß, and interferon gamma (IFN-?). Infection of endothelial cells by *R. rickettsii* induces surface E-selectin expression and procoagulant activity. Cytokine release and vascular selectin expression result in infiltration of the damaged endothelial cells by lymphocytes, macrophages, and occasionally neutrophils. Local inflammatory and immune responses have been suspected as contributors to vascular injury in the rickettsioses; however, the benefits of effective inflammation and immunity outweigh any potential damage mediated by host responses directed toward elimination of local infection. Blockade of TNFa and IFN-? action in animal models diminishes survival and increases the morbidity of spotted fever group infections, probably by abrogating upregulation of nitric oxide synthase and arginine-dependent intracellular killing events. Important mediators for control of infection include direct contact of infected endothelial cells with CD8 T lymphocytes that produce perforin and NK cells that produce IFN-?. *Rickettsia* infection leads to upregulated expression of procoagulant molecules on the surfaces of infected endothelial cells. This is associated with induction of tissue plasminogen activator inhibitor and reduction in plasminogen activator levels that promote coagulation factor consumption, platelet adhesion, and leukocyte emigration and may result in a clinical syndrome similar to disseminated intravascular coagulation.

Clinical Manifestations.

The incubation period in children varies from 2–14 days, with a median of 7 days. The illness is initially nonspecific with headache, fever, anorexia, myalgias, and restlessness. Gastrointestinal symptoms including nausea, vomiting, diarrhea, and abdominal pain occur frequently (39–63%) early in the disease. Often considered the hallmark of rickettsial infection, skin rash is detected usually after the 3rd day of illness, and the typical clinical triad of headache, fever, and rash that is observed in 44% of patients overall is documented in only 3% of all patients at presentation. Approximately 10–15% of patients never develop rash or have atypical cutaneous manifestations. The site of the tick bite is usually inapparent. Discrete, pale, rose-red blanching macules or maculopapules appear initially, characteristically on the extremities, including the ankles, wrists, or lower legs (Fig. 210–1*A*). The rash then spreads rapidly to involve the entire body, including the soles and palms. After several days, the rash becomes more petechial or hemorrhagic, sometimes with palpable purpura (see Fig. 210–1*B*). Fever and headache persist and are accompanied by severe myalgia and malaise. Splenomegaly and hepatomegaly are present in approximately 33% of patients. In severe disease, the petechiae may enlarge into ecchymoses, which may become necrotic. Severe vascular obstruction secondary to the rickettsial vasculitis and thrombosis is infrequent but may result in gangrene of the digits, earlobes, scrotum, nose, or an entire limb. Central nervous system infection often produces changes in the sensorium, and delirium or coma may supervene. In addition, patients may manifest ataxia, meningismus, or auditory deficits. Other severe manifestations include facial edema, myocarditis, acute renal failure, vascular collapse, and pneumonitis with noncardiogenic pulmonary edema.

Fulminant RMSF, defined as *R. rickettsii* infection leading to death in <5 days, may occur, especially among persons with glucose-6-phosphate dehydrogenase (G6PD) deficiency. The clinical course of fulminant RMSF is characterized by profound coagulopathy and extensive visceral thrombosis with kidney, liver, or respiratory failure. Clinical features associated with a fatal outcome include hepatomegaly, jaundice, stupor, acute renal failure, respiratory distress, and a disseminated intravascular coagulation–like syndrome in the absence of host inflammatory response.

Diagnosis.

Severe or fatal rickettsial infections are associated with delays in diagnosis and treatment. The diagnosis of RMSF should be considered in patients presenting during the spring through fall with an acute febrile illness accompanied by headache and myalgia, particularly if they were exposed to ticks in known endemic regions, were in forested or tick-infested rural areas, or had contact with a dog. A history of tick exposure and the appearance of a rash, especially on the palms or soles, together with laboratory findings of normal or low leukocyte count with a marked left shift, a relatively low or decreasing

Figure 210.1-1 Patient with Rocky Mountain spotted fever. *A*, Rash early in the illness that is prominent on the extremities. *B*, Later in the course of Rocky Mountain spotted fever, the rash may become hemorrhagic or purpuric. (Courtesy of Debra Karp Skopicki, MD.)

platelet count, and a low serum sodium concentration, are clues that are sometimes helpful in distinguishing RMSF from some other acute infections. In patients with no rash or in dark-skinned individuals in whom a rash may be difficult to appreciate, the diagnosis may be exceptionally elusive and delayed. One half of pediatric fatalities occur within 9 days of onset of symptoms. On occasion, rickettsial vascular infection predominates in a single organ or system, erroneously suggesting a localized process such as appendicitis or cholecystitis. A thorough evaluation usually reveals evidence of a systemic process and can avoid unnecessary surgical intervention.

An abnormally low platelet count, normal to slightly low leukocyte count, and low serum sodium concentration are present in about half of patients and may be early clues to the diagnosis. Most other clinical laboratory findings are nonspecific and vary depending on the degree of specific organ involvement. RMSF may cause meningoencephalitis that presents with a cerebrospinal fluid pleocytosis with a predominance of mononuclear cells. However, no single laboratory test completely establishes an early diagnosis. Thus, treatment should not be withheld pending laboratory results for a patient with clinically suspected illness.

If a rash is present, a vasculotropic rickettsial infection can be diagnosed as early as day 3 of illness by immunohistologic demonstration of specific rickettsial antigen in

the endothelium in skin biopsies of petechial lesions. The procedure may be performed by immunofluorescence or immunoperoxidase and is very specific. However, the sensitivity of this method is probably not greater than 70%, and it can be adversely influenced by prior antimicrobial therapy, suboptimal biopsy of skin lesions, and examination of insufficient tissue because the infection may be very focal. Moreover, selection of an appropriate biopsy site may be difficult because approximately 10–15% of patients with RMSF either do not have a rash or have an atypical rash. Evaluation of blood for *R. rickettsii* nucleic acids by polymerase chain reaction demonstrates little sensitivity beyond that of immunohistology, probably because the level of rickettsemia is generally very low (<6 rickettsia/mL).

Radiologic evaluations often reveal no significant abnormalities, and when present on CT or MR neuroimaging studies, the findings are generally subtle and do not alter treatment. However, in one series, 17% of patients with radiologic abnormalities (e.g., cerebral edema, meningeal enhancement, and prominent perivascular spaces) died of RMSF.

Because treatment must be initiated on the clinical diagnosis alone, confirmation is most often accomplished by serologic tests. Diagnostic serologic criteria include a fourfold increase in antibody titer, usually by indirect fluorescent antibody (IFA) assay, in acute and convalescent sera (2–4 wk apart) or a single elevated IFA titer of =1:64 in convalescent serum. A case is considered probable if a single titer of =1:128 is found. Weil-Felix antibody testing should not be performed because it lacks both sensitivity and specificity.

DIFFERENTIAL DIAGNOSIS.

Other rickettsial infections are easily confused with RMSF, especially all forms of human ehrlichiosis and murine typhus. RMSF can mimic many diseases; among the most important of these are meningococcemia, measles, and enteroviral exanthemas. Negative blood cultures may aid in reaching a correct diagnosis. However, *R. rickettsii* may cause aseptic meningitis and elicit lymphocytic pleocytosis, suggesting a viral etiology and further confounding the diagnosis. Other diseases sometimes included in the differential diagnosis are typhoid fever, secondary syphilis, Lyme disease, leptospirosis, scarlet fever, toxic shock syndrome, rheumatic fever, rubella, Kawasaki disease, idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, Henoch-Schönlein purpura, hemolytic uremic syndrome, aseptic meningitis, acute gastrointestinal illness, acute abdomen, hepatitis, infectious mononucleosis, dengue fever, and drug reactions.

Treatment.

The time-proven effective therapies for RMSF are tetracycline and chloramphenicol. Both agents have drawbacks for pediatric therapy in that tetracycline and doxycycline may be associated with tooth discoloration, whereas chloramphenicol is associated rarely with aplastic anemia. Recent controversial evaluations reveal that mortality is significantly increased when chloramphenicol alone is used compared with tetracycline alone, even when other factors such as severity are considered. Moreover, chloramphenicol is no longer available as an oral preparation in the United States. Doxycycline can be used for RMSF safely in children younger than 9 yr of age, because tooth discoloration is dose-dependent, and it is unlikely that children younger than 9 yr of age will require multiple courses.

Greater morbidity and excess mortality are associated with sulfonamide therapy, which is discouraged. Other antibiotics including penicillins, cephalosporins, and aminoglycosides are not effective. The use of alternative antimicrobial agents such as quinolones and the new macrolides (azithromycin and clarithromycin) for RMSF has not been evaluated.

Recommended treatment regimens for RMSF are doxycycline orally or intravenously (two loading doses of 2.2?mg/kg/dose at 12-hr intervals followed by 2.2?mg/kg/24?hr divided q 12?hr PO or IV; maximum: 300?mg/dose); tetracycline orally (25–50?mg/kg/24?hr divided q 6?hr PO; maximum: 2?g/24?hr); or chloramphenicol intravenously (50–100?mg/kg/24?hr divided q 6?hr IV; maximum: 3?g/24?hr), which must be monitored to maintain serum concentrations between 10 and 30?µg/mL. Therapy should be continued for a minimum of 5 days and until the patient has been afebrile for at least 2–4 days to avoid relapse, especially in patients who were treated early. Patients treated with one of these regimens usually become afebrile within 48?hr, and thus the entire period of therapy usually lasts <10 days.

SUPPORTIVE CARE.

Most infections resolve rapidly with appropriate antimicrobial therapy and do not require hospitalization or other supportive care. On occasion, severe infections require intensive care. Particular attention to hemodynamic status is required in severely ill children because iatrogenic pulmonary or cerebral edema is easy to precipitate given pre-existing diffuse microvascular lung and meningovascular and cerebrovascular injury. Judicious use of corticosteroids for meningoencephalitis has been advocated by some, although no controlled trials have been conducted.

Complications.

Complications of RMSF include noncardiogenic pulmonary edema from pulmonary microvascular leakage, cerebral edema from meningoencephalitis, and multiorgan damage (hepatitis, pancreatitis, cholecystitis, epidermal necrosis, and gangrene) partly mediated by rickettsial vasculitis or the accumulated effects of hypoperfusion and ischemia (acute renal failure). Long-term neurologic sequelae are more likely to occur in patients who have been hospitalized for =2 weeks and include paraparesis, hearing loss, peripheral neuropathy, bladder and bowel incontinence, cerebellar, vestibular, and motor dysfunction, and language disorders.

Prognosis.

Delays in diagnosis and therapy are significant factors associated with death or severe illness. Before the advent of effective antimicrobial therapy for RMSF, the case fatality rate was 10–40%. CDC statistics suggest stabilization of this rate between 2% and 7%; however, a case fatality rate of 8.5% was documented in Texas from 1986 through 1996. Evidence exists that diagnosis based upon serology alone underestimates the true mortality of RMSF. Fatalities occur despite the availability of effective therapeutic agents, indicating the need for vigilant clinical suspicion and a low threshold for early and aggressive therapy in clinically suspected cases. Even with administration of appropriate antimicrobials, delayed therapy may

allow irreversible vascular or end-organ damage and long-term sequelae or death. Early therapy in uncomplicated cases ordinarily leads

to rapid defervescence within 1–3 days and recovery within 7–10 days.

Prevention.

No vaccines are available. Prevention of RMSF is best accomplished by eliminating tick infestations of dogs, avoiding wooded or grassy areas where ticks reside, using insect repellents containing DEET, wearing protective clothing, and carefully inspecting children who have been playing in the woods or fields.

Prompt and complete removal of attached ticks helps reduce the risk of transmission because reactivation to virulence of rickettsiae in the tick requires at least several hours to days of exposure to body heat or blood. Contrary to popular belief, the application of petroleum jelly, 70% isopropyl alcohol, fingernail polish, or a hot match are not effective in removing ticks from persons or animals. A tick can be safely removed by grasping the mouthparts with a pair of forceps at the site of cutaneous contact and applying gentle and steady retraction to remove the entire tick and mouth parts. The site of attachment should then be disinfected. Ticks should not be squeezed or crushed because their fluids may be infectious. Tick disposal should be accomplished by soaking the tick in alcohol or flushing it down the toilet, followed by good hand washing. Prophylactic antimicrobial therapy should not be administered because tetracyclines and chloramphenicol are only rickettsiostatic; such therapy simply delays the onset of illness and confuses the clinical picture by prolonging the incubation period.

210.2 Mediterranean Spotted Fever or Boutonneuse Fever (*Rickettsia conorii*)

The disease caused by *R. conorii* is known by various geographically recognized names, including Mediterranean spotted fever, or MSF, boutonneuse fever, Kenya tick typhus, and Indian tick typhus. It is a moderately severe vasculotropic rickettsiosis that is often initially associated with an eschar at the site of the tick bite

Etiology.

MSF is caused by systemic endothelial cell infection by the obligate intracellular bacterium *R. conorii*. Similar illnesses are distributed globally but are caused by distinct yet related species including *R. sibirica* in Russia, China, Mongolia, and Pakistan, *R. australis* or *R. honei* in Australia, *R. japonica* in Japan, and *R. africae* in South Africa (see Table 210–1). These species are closely related to *R. rickettsii* by analysis of antigens and DNA sequences.

Epidemiology.

R. conorii is distributed over a large geographic region including India, Pakistan, Russia, Ukraine, Georgia, Israel, Ethiopia, Kenya, South Africa, Morocco, and southern Europe.

MSF has demonstrated a steadily increasing incidence since 1980 in southern Europe and has reached seroprevalence rates of 11–26% in some areas. The peak incidence is seen during July and August in the Mediterranean basin, but in other regions it occurs during warm seasons when ticks are active. Many cases of imported infection have been documented in travelers to endemic regions, especially those who go on safari in regions with high grass and bush land.

TRANSMISSION.

Transmission occurs after the bite of the brown dog tick, *R. sanguineus*, or other tick species including *Dermacentor, Haemaphysalis, Amblyomma, Hyalomma*, and *Ixodes*. A strong correlation exists among the incidence of boutonneuse fever, infected ticks, and evidence of infection in both dogs and humans, implicating the household dog as a potential vehicle for transmission.

Pathogenesis.

The underlying pathology for MSF is nearly identical to that of RMSF, except that eschars are often identified at the primary site of tick bite and inoculation of the rickettsiae. The histopathology of the tick bite lesion includes necrosis of dermal and epidermal tissues with a superficial crust, and dermal structures are densely infiltrated by lymphocytes, histiocytes, and scattered neutrophils, among damaged capillaries and venules. Immunohistochemical stains confirm that the lesions contain rickettsia-infected endothelial cells, although the remnant structure of the vasculature may not be apparent owing to the extensive inflammation and necrosis. The necrosis results from both direct rickettsia-mediated vasculitis and extensive local inflammation. Rickettsiae released at this site have ready access to lymphatics or venous blood and disseminate to cause a systemic infection.

Clinical Manifestations.

Patients with MSF typically experience fever, headache, myalgias, and a maculopapular rash, which appears 3–5 days after onset of symptoms. In about 70% of patients, an eschar, the tache noire, at the initial site of tick attachment and regional lymphadenopathy are present. Although it was previously considered benign and self-limited, this infection may cause severe disease in up to 6% of infected individuals. It is characterized by findings similar to RMSF, including purpuric skin lesions, neurologic signs, respiratory distress, acute renal failure, severe thrombocytopenia, and death in 1.4–5.6% of cases. As with RMSF, a particularly malignant form occurs in patients with G6PD deficiency and in individuals with other underlying conditions such as alcoholic liver disease or diabetes mellitus.

Diagnosis.

Laboratory diagnosis of MSF and the other spotted fever group rickettsioses is the

same as that for Rocky Mountain spotted fever and may be accomplished by immunohistologic demonstration of rickettsiae on skin biopsy, immunocytologic demonstration of *R. conorii* (and potentially other spotted fever group rickettsiae) in circulating endothelial cells, in vitro cultivation by means of centrifugation-assisted shell vial tissue culture, or the demonstration of serum antibodies to spotted fever group rickettsiae in convalescent patients. Reagents useful for the diagnosis of RMSF in the United States or MSF in Europe, Africa, and Asia can be used effectively for the diagnosis of infections by most members of the spotted fever group of rickettsiae.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis is similar to that of RMSF with the inclusion of conditions associated with single eschars that may be seen also with other rickettsioses such as rickettsialpox, African tick-bite fever, or scrub typhus. The recently described spotted fever rickettsia, *R. africae*, causes a milder illness and is often associated with multiple eschars; it may be observed in African locations where MSF also occurs.

Treatment.

MSF is effectively treated with tetracycline, doxycycline, chloramphenicol, ciprofloxacin, ofloxacin, pefloxacin, levofloxacin, azithromycin, or clarithromycin. Regimens for doxycycline, tetracycline, and chloramphenicol are as described for RMSF. Azithromycin (10?mg/kg/24?hr once daily PO) and clarithromycin (15?mg/kg/24?hr divided bid PO) are alternatives. Specific quinolone regimens effective for children have not been established. Intensive care may be required for hemodynamic management of severely affected individuals.

Complications.

The complications of MSF are similar to those of RMSF. The case fatality rate is approximately 2%. Particularly severe infections have been noted in patients with underlying medical conditions including G6PD deficiency and diabetes mellitus.

Prevention.

MSF is transmitted by tick bites, and prevention is the same as recommended for RMSF. No vaccine is currently available.

210.3 Rickettsialpox (*Rickettsia akari*)

Rickettsialpox is caused by *R. akari*, which is transmitted by the mouse mite, *Allodermanyssus sanguineus*. The mouse host for this

mite is widely distributed in cities in the United States, Europe, and Asia. Seroepidemiologic studies suggest a high prevalence for this infection in urban settings; however, the disease is usually mild and is infrequently diagnosed. Unlike most forms of spotted fever rickettsiosis, an important target cell for infection is the macrophage.

Rickettsialpox is best known because of its association with a varicelliform rash. In fact, this rash is a modified form of an antecedent typical macular or maculopapular rash like those seen in other vasculotropic rickettsioses. At presentation, most patients have fever, headache, and chills. There may be a papular or ulcerative lesion at the initial site of inoculation in up to 90% of cases, which may be associated with regional lymphadenopathy. In some patients, the maculopapular rash, which is distributed over the trunk, head, and extremities, may become vesicular. The infection resolves spontaneously even without therapy. Complications and fatalities are rare.

Chapter 211 - Scrub Typhus (*Orientia tsutsugamushi*)

Scrub typhus is a common and important febrile infectious disease in many parts of the eastern hemisphere. Recent reports suggest that natural resistance to doxycycline and other antibiotics make selection of appropriate antimicrobial therapy difficult. Some evidence suggests that concurrent scrub typhus may inhibit the replication of HIV.

Etiology.

The causative agent of scrub typhus, or Tsutsugamushi fever, is *Orientia tsutsugamushi*, which is distinct from other spotted fever and typhus group rickettsiae. *O. tsutsugamushi* lacks both lipopolysaccharide and peptidoglycan in its cell wall. Like other vasculotropic *Rickettsia*, *O. tsutsugamushi* infects endothelium and elicits vasculitis, the predominant clinicopathologic feature of the disease. However, the organism also infects cardiac myocytes and macrophages, raising questions about how these findings may explain the clinical manifestations.

Epidemiology.

Approximately 1 million infections occur each year, and it is estimated that more than 1 billion people are at risk. Scrub typhus occurs mostly in the Far East, including areas delimited by a triangle connecting Korea, Pakistan, and northern Australia. Aside from infections in these tropical and subtropical regions, the disease occurs in Japan, the Primorye of far eastern Russia, Tajikistan, Nepal, and nontropical China including Tibet. Cases imported to the United States and other parts of the world are reported.

TRANSMISSION.

O. tsutsugamushi is transmitted via the bite of the larval stage (chigger) of a trombiculid mite (*Leptotrombidium*), which serves as both vector and reservoir. Transovarial transmission (passage of the organism from infected ticks to their progeny) occurs efficiently, and transmission of the organism to mites from infected animals is poor; however, a role for horizontal transmission from infected rodent hosts to uninfected mites has not been disproved. Multiple serotypes are recognized, and some share antigenic cross reactivity.

Pathogenesis.

The pathogenesis of scrub typhus is uncertain. Recent studies inidicate that the process is stimulated by a disseminated rickettsial infection of vascular endothelial cells that corresponds to the distribution of disseminated vasculitic and perivascular inflammatory lesions observed in histopathologic examinations. The major result of the vascular injury appears in autopsy series to be hemorrhage. However, it is very likely that the vascular injury initiated by the rickettsial infection results in significant vascular leakage and compromise and is further confounded by the waxing immune and inflammatory reactions. The net result is significant vascular compromise and ensuing end-organ injury, most often manifest in the brain and lungs, as with other vasculotropic rickettsioses.

Clinical Manifestations.

Scrub typhus may be mild or severe. After an incubation period of 6–21 days, the rickettsiae proliferate at the site of the chigger bite to form in <50% of cases a necrotic eschar with an erythematous rim. The onset of illness usually becomes manifest by fever, headache, and sometimes myalgia, cough, and gastrointestinal symptoms. Regional or generalized lymphadenopathy is common. A maculopapular rash is present in <50% of patients and involves the trunk and extremities and infrequently the hands or face. Complications include severe meningoencephalitis, myocarditis, and interstitial pneumonitis. The case fatality rate in untreated patients may be as high as 30%.

Diagnosis.

The diagnosis is usually confirmed by indirect fluorescent antibody assay or immunoperoxidase serologic tests using various serotypes of *O. tsutsugamushi* as antigen. The differential diagnosis includes other rickettsioses, tularemia, anthrax, dengue, leptospirosis, typhoid fever, malaria, and infectious mononucleosis.

Treatment.

Recommended treatment regimens for scrub typhus are doxycycline orally or intravenously (two loading doses of 2.2?mg/kg/dose at 12-hr intervals followed by 2.2?mg/kg/24?hr divided q 12?hr PO or IV; maximum: 300?mg/dose); tetracycline orally (25–50?mg/kg/24?hr divided q 6?hr PO; maximum: 2?g/24?hr); or chloramphenicol intravenously (50–100?mg/kg/24?hr divided q 6?hr IV; maximum: 3?g/24?hr), which must be monitored to maintain serum concentrations between 10 and 30?µg/mL. Therapy should be continued for a minimum of 5 days and until the patient has been afebrile for at least 2–4 days to avoid relapse, especially in patients who were treated early. Patients treated with one of these regimens usually become afebrile within 48?hr, and thus the entire period of therapy usually lasts <10 days.

Some reports suggest that more virulent or potentially doxycycline-resistant strains may have emerged. Recent clinical trials have shown, in regions where doxycycline resistance is frequent, that azithromycin may be as effective, and that rifampicin is superior to doxycycline. Intensive care may be required for hemodynamic

management of severely affected individuals.

Complications.

Serious complications of scrub typhus include pneumonitis, acute respiratory distress syndrome, acute renal failure, myocarditis, a septic shock-like syndrome, encephalomyelitis, and death.

Prevention.

Prevention is based on avoidance of the chiggers that transmit *O. tsutsugamushi*. Protective clothing is the next most useful mode of prevention. No vaccine is currently available.

Chapter 212 - Typhus Group Rickettsioses

Members of the typhus group of rickettsiae pathogenic for humans (see Table 210–1) include *Rickettsia typhi* (murine typhus) and *R. prowazekii* (epidemic typhus). *R. typhi* is flea-transmitted, whereas *R. prowazekii* is transmitted to humans in the feces of body lice. Epidemic typhus (*R. prowazekii*) is widely considered to be the most virulent of all *Rickettsia*, with a high mortality rate even with treatment. Murine typhus is moderately severe and perhaps one of the most under-recognized infections in the world. The entire genome of *R. prowazekii* has been sequenced, allowing a number of novel observations regarding genes required for obligate intracellular bacterial life.

212.1 Murine Typhus (*Rickettsia typhi*)

Etiology.

Murine typhus is caused by *Rickettsia typhi*, a rickettsia that is transmitted from infected fleas to rats or opossums and back to fleas. Transovarial transmission (passage of the organism from infected ticks to their progeny) in fleas is inefficient, and thus, transmission depends on distribution by the flea to uninfected mammals, which become transiently rickettsemic and, in turn, transmit the organism to uninfected fleas.

A novel agent within the genus *Rickettsia* has been identified as a cause of a murine typhus–like illness in south Texas and is recognized increasingly worldwide. This new rickettsia, *R. felis*, is genetically a spotted fever group rickettsia and is capable of highly efficient transovarial transmission in cat fleas. This organism is found in cat fleas obtained from areas endemic for murine typhus in the United States.

Epidemiology.

Murine typhus has a worldwide distribution and occurs especially in warm coastal ports where it is maintained in a cycle involving rat fleas (*Xenopsylla cheopis*) and rats (*Rattus* species). Peak incidence occurs when rat populations are highest during spring, summer, and fall. In the United States, the disease is most prevalent in south Texas and southern California, although sporadic cases have been reported in most other states as well. In the coastal areas of south Texas, the disease is seen predominantly from March through June and is associated with opossums, cats, and cat fleas (*Ctenocephalides felis*). Seroepidemiologic testing has shown a high prevalence in southeastern U.S. urban settings, expanding the endemic areas in which pediatricians must be alert for this infection.

TRANSMISSION.

Human acquisition of murine typhus occurs when rickettsiae-infected flea feces contaminate flea bite wounds.

Pathogenesis.

R. typhi is a vasculotropic rickettsial species that causes disease in much the same way as does *R. rickettsii* (Chapter 225.1). *R. typhi* organisms in flea feces deposited on the skin as part of the flea feeding reflex are inoculated into the pruritic flea bite wound. After an interval during which local proliferation occurs, the rickettsiae spread systemically to infect the endothelium in many tissues. As with spotted fever group rickettsiae, typhus group rickettsiae infect endothelial cells but polymerize actin poorly for intracellular mobility and probably cause cellular injury by mechanical lysis owing to the accumulation of large numbers of rickettsiae within the endothelial cell cytoplasm. Intracellular infection leads to endothelial cell damage and recruitment of inflammatory cells and vasculitis. The inflammatory cell infiltrates bring in a number of effector cells, including macrophages that produce proinflammatory cytokines, and CD4, CD8, and NK lymphocytes, which may produce immune cytokines such as interferon-? or participate in cell-mediated cytotoxic responses. Intracellular rickettsial proliferation of typhus group rickettsiae is inhibited by cytokine-mediated, nitric oxide–dependent and –independent mechanisms.

Pathologic findings include the presence of systemic vasculitis in response to the presence of rickettsiae within endothelial cells. This is manifest as interstitial pneumonitis, interstitial nephritis, myocarditis, meningitis, and mild hepatitis with periportal lymphohistiocytic infiltrates. As vasculitis and inflammatory damage accumulate, multiorgan damage may ensue.

Clinical Manifestations.

Murine typhus is a moderately severe infection that is similar to other vasculotropic rickettsioses. The infection in children generally appears to be mild. The incubation period may vary from 1–2 wk. The initial presentation is often nonspecific, with fever of undetermined origin the most frequent presentation. Pediatric patients exhibit the typically important clues for murine typhus somewhat less frequently than for the other vasculotropic rickettsioses, including rash (48–80%), myalgias (29–57%), vomiting (29–45%), cough (15–40%), headache (19–77%), and diarrhea or abdominal pain (10–40%). Although neurologic involvement may be a frequent finding in adults with murine typhus, photophobia, confusion, stupor, coma, seizures, meningismus, and ataxia are seen in <17% of hospitalized and <6% of infected children treated as outpatients. A petechial rash is observed in only up to 13% of children, and the usual appearance is that of macules or maculopapules distributed on the trunk and extremities. The rash may involve both the soles and palms on rare occasions.

Diagnosis.

As for other vasculotropic rickettsioses, delays in diagnosis and therapy are associated with increased morbidity and mortality; thus, diagnosis must be based on clinical suspicion. Occasionally, patients present with findings suggestive of pharyngitis, bronchitis, hepatitis, gastroenteritis, or sepsis; thus, the differential diagnosis may be extensive.

Although they are nonspecific, laboratory findings that may be helpful include mild leukopenia (36–40%) with a moderate left shift, mild to marked thrombocytopenia (43–60%), hyponatremia (20–66%), hypoalbuminemia (46–87%), and elevated aspartate aminotransferase (82%) and alanine aminotransferase (38%). Elevations in serum urea nitrogen are usually due to prerenal mechanisms.

Confirmation of the diagnosis is usually accomplished in convalescence by indirect fluorescent antibody assay serology. Research tools now being evaluated include polymerase chain reaction amplification of rickettsial nucleic acids in acute phase blood, rickettsial culture by the centrifugation-assisted shell vial assay, and immunohistology on skin biopsy.

Treatment.

Therapy for murine typhus includes the use of tetracyclines or chloramphenicol and is similar to that recommended for Rocky Mountain spotted fever. No controlled trials of other antimicrobial agents have been performed; however, ciprofloxacin has been used effectively to treat murine typhus, and in vitro experiments suggest that minimal inhibitory concentrations of azithromycin and clarithromycin for *R. typhi* should be easily achieved.

Recommended treatment regimens for murine typhus include doxycycline orally or intravenously (2.2?mg/kg/24?hr divided bid PO or IV; maximum: 300?mg/dose), tetracycline orally (25–50?mg/kg/24?hr

divided q 6?hr PO; maximum: 2?g/24?hr), and chloramphenicol intravenously (50–100?mg/kg/24?hr divided q 6?hr IV; maximum: 3?g/24?hr). Therapy should be continued for a minimum of 5 days or until the patient has been afebrile for at least 2–4 days to avoid relapse, especially in patients treated early.

SUPPORTIVE CARE.

Although usually mild, 7% of children with murine typhus may require intensive care to manage complications such as meningoencephalitis or a disseminated intravascular coagulation–like condition. As for other rickettsial infections with significant systemic vascular injury, careful hemodynamic management is mandatory to avoid pulmonary or cerebral edema.

Complications.

Complications of murine typhus in pediatric patients are infrequent; however, relapse, stupor, facial edema, dehydration, and meningoencephalitis have been

reported.

Prevention.

Control of murine typhus has been dependent on elimination of the rat and rat flea reservoir, and this remains an important component of control. However, with the recognition of cat fleas as potentially significant reservoirs and vectors, the presence of these flea vectors and their mammalian hosts in suburban and urban areas where close human exposures occur will probably pose increasingly important control problems.

212.2 Epidemic Typhus (*Rickettsia prowazekii*)

Etiology.

Humans have long been considered the principal or only reservoir of *R. prowazekii*, the causative agent of epidemic or louse-borne typhus, and its recrudescent form, Brill-Zinsser disease, also known as Brill disease. Another reservoir has recently been identified in flying squirrels, implying that a sylvatic cycle with small rodents and their ectoparasites also exists. The rickettsia is the most pathogenic of the genus, and multiplies to very high quantities before the mechanical rupture of infected endothelial cells. The genome of *R. prowazekii* is thought to be losing functional genes as it has adapted to its unique intracellular niche. *R. prowazekii* is now clearly recognized as a genetic relative of the eukaryotic mitochondrion.

Epidemiology.

The infection is characteristically seen in winter or spring or during times of poor hygienic practices associated with crowding, war, famine, extreme poverty, and civil strife. A cause of some sporadic cases of a mild, typhus-like illness has been confirmed as *R. prowazekii*; such cases are associated with exposure to flying squirrels harboring infected lice or fleas. The *R. prowazekii* organisms isolated from these squirrels appear to be genetically different from isolates obtained during typical outbreaks.

Most cases of epidemic typhus from 1981–1997 have been sporadic, but outbreaks have been identified in Africa (Ethiopia, Nigeria, Burundi), Mexico, Central America, South America, eastern Europe, Afghanistan, Russia, northern India, and China. Following the Burundi civil war in 1993, there were approximately 35,000 cases of epidemic typhus diagnosed among 764,334 displaced refugees.

TRANSMISSION.

Human body lice (*Pediculus humanus* subsp. *corporis*) become infected by feeding on rickettsemic persons. The ingested rickettsiae infect the midgut epithelial cells of the lice and are passed into the feces, which are introduced in turn into a susceptible human host through abrasions or perforations in the skin, through the conjunctivae, or rarely through inhalation of dried infected louse excreta present in clothing, bedding, or furniture.

Clinical Manifestations.

Epidemic typhus fever may be a mild or severe disease in children. The incubation period is usually <14 days. The typical clinical manifestations include fever, severe headache, abdominal tenderness, and rash in most patients, as well as chills (82%), myalgias (70%), arthralgias (70%), anorexia (48%), nonproductive cough (38%), dizziness (35%), photophobia (33%), nausea (32%), abdominal pain (30%), tinnitus (23%), constipation (23%) meningismus (17%), visual disturbances (15%), vomiting (10%), and diarrhea (7%). However, investigation of recent African outbreaks has shown a lower frequency of rash (25%) and a high frequency of delirium (81%) and cough associated with pneumonitis (70%). The rash is initially pink or erythematous and blanches. In one third of patients, red, nonblanching macules and petechiae appear predominantly on the trunk. Infections identified during the preantibiotic era typically produced a variety of central nervous system findings including delirium (48%), coma (6%), and seizures (1%). Estimates of case fatality rates range between 3.8% and 20% in outbreaks.

Brill-Zinsser disease is an unusual form of typhus that becomes recrudescent months to years after the primary infection. When rickettsemic, these infected individuals may transmit the agent to lice.

Treatment.

Recommended treatment regimens for epidemic or sylvatic typhus are identical to those used for murine typhus: doxycycline orally or intravenously (2.2?mg/kg/24?hr divided q 12?hr PO or IV; maximum: 300?mg/dose), tetracycline orally (25–50?mg/kg/24?hr divided q 6?hr PO; maximum: 2?g/24?hr), or chloramphenicol intravenously (50–100?mg/kg/24?hr divided q 6?hr IV; maximum: 3?g/24?hr). Therapy should be continued for a minimum of 5 days and until the patient has been afebrile for at least 2–4 days to avoid relapse, especially in patients treated early. Good evidence exists that doxycycline as a single 200-mg oral dose is also efficacious.

Prevention.

Immediate destruction of vectors with an insecticide is important in the control of an epidemic. For epidemic typhus, antibiotic therapy and delousing measures will interrupt transmission, reduce the prevalence of infection in the human reservoir, and diminish the impact of an outbreak. Dust containing excreta from infected lice is capable of transmitting typhus, and care must be taken to prevent its inhalation.

Chapter 213 - Ehrlichiosis and Anaplasmosis

Etiology.

In 1987, clusters of bacteria confined within cytoplasmic vacuoles of circulating leukocytes (morulae), particularly mononuclear leukocytes, were detected in the peripheral blood of a severely ill patient with suspected Rocky Mountain spotted fever (RMSF). The etiologic agent of the infection and of other

cases in which serologic tests could not prove RMSF was found to be similar to a canine pathogen in the genus *Ehrlichia*. In 1990, a new species, *Ehrlichia chaffeensis*, was cultivated and identified as the predominant agent of human ehrlichiosis. Seroepidemiologic investigation has shown that in some geographic areas *E. chaffeensis* infections occur more frequently than RMSF, and the infection is strongly associated with tick bites.

In 1994, another similar species was recognized in human blood with the observation of morulae only in circulating neutrophils. Serologic investigation in these cases revealed the absence of *E. chaffeensis* antibodies, and most had serologic reactions to *E. phagocytophila* and *E. equi*, previously known only as pathogens of ruminant and horse granulocytes, respectively. DNA of these bacteria was also found in the blood of many infected persons. In 1996, the agent was cultivated in vitro, and based upon genetic studies in 2001, the human agent and the two veterinary pathogens were unified into a single species and placed into the genus *Anaplasma* under the name *Anaplasma phagocytophilum*.

In 1996, a veterinary pathogen of canine neutrophils, *Ehrlichia ewingii*, was identified as the causative agent of some human infections initially thought to be due to *E. chaffeensis*. The agent is occasionally identified in peripheral blood neutrophils and the infection is generally milder and involves children or adults with pre-existing immunosuppression, including organ transplant recipients or persons with HIV infection. Although not yet cultivated in vitro, it is serologically cross reactive with *E. chaffeensis*.

Although bacteria assigned to various genera cause these infections, the name **ehrlichiosis** is applied to all. To differentiate among these infections, disease caused by *E. chaffeensis*, which infects predominantly monocytic cells, is called **human monocytic ehrlichiosis (HME)**, disease caused by *Anaplasma*

phagocytophilum is called **human anaplasmosis**, formerly **granulocytic ehrlichiosis (HGE)**, and disease caused by *E. ewingii* has received various names, including **ehrlichiosis ewingii**.

All of these bacteria are now classified in the Anaplasmataceae family, and share many characteristics including transmission by tick bite. In addition, *Neorickettsia* (formerly *Ehrlichia*) *sennetsu* is another related bacterium in this family that is a rare cause of human disease, but is not tick-transmitted. In general, these are small, pleomorphic, obligate intracellular bacteria that possess gram-negative–type cell walls. *E. chaffeensis* induces the endosome to enter a receptor recycling pathway that avoids phagosome-lysosome fusion and allows the growth of a cytoplasmic aggregate of bacteria called a morula. Little is known about the vacuoles in which *A. phagocytophila* and *E. ewingii* grow. These bacteria are pathogens of hematopoietic cells in mammals, and characteristically each species has a specific host cell affinity: *E. chaffeensis* and *N. sennetsu* infect mononuclear phagocytes, and *A. phagocytophila* and *E. ewingii* infect neutrophils. Infection leads to modifications in function of the host cell, and insufficient levels of infection are usually obtained to account directly for the severity and pathology observed. Thus, an increasing body of data suggests that host immune and inflammatory reactions may in part account for many of the clinical manifestations in all forms of ehrlichiosis.

Epidemiology.

Infections with *E. chaffeensis* occur in broad areas across the southeastern, south central, and mid-Atlantic states, in a distribution that parallels that of RMSF. Although suspected cases with appropriate serologic findings have been reported in Europe, Africa, and the Far East, no other data supports the existence of this human disease outside of North America. Anaplasmosis is the most frequently recognized of all forms of ehrlichiosis and is found mostly in the northeast and upper midwestern United States, but infections have now been identified in northern California, the mid-Atlantic, and broadly across Europe, confirming that the agent is widely distributed. Human infections with *E. ewingii* have only been identified in areas where *E. chaffeensis* also exist, perhaps owing to a shared tick vector.

Although the median age of patients with ehrlichiosis and anaplasmosis is generally older (>42 yr), many infected children have been identified. Little is known about the epidemiologic aspects of *E. ewingii* infection. As expected, all infections are highly associated with tick exposure and tick bites, and are identified predominantly during May through September; a second peak of anaplasmosis occurs in late October through December because of activity of the adult stage of *Ixodes scapularis* ticks during this time.

TRANSMISSION.

The predominant tick species that harbors *E. chaffeensis* and *E. ewingii* is *Amblyomma americanum*, the Lone Star tick. Additional vectors such as *Dermacentor variabilis*, the American dog tick, have not been proved but may explain the presence of HME outside the known range of *A. americanum*. The tick vectors of *A. phagocytophilum* are *Ixodes*, including *I. scapularis* (black-legged or deer tick) in the eastern United States, *I. pacificus* (western black-legged tick) in the western United States, *I. ricinus* (sheep tick) in Europe, and potentially *I. persulcatus* in Eurasia.

Ehrlichia and *Anaplasma* species are maintained in nature predominantly by horizontal transmission (tick to mammal to tick) because the organisms are not transmitted to the progeny of infected adult female ticks. The major reservoir host for *E. chaffeensis* is the white-tailed deer *(Odocoileus virginianus)*, which is found abundantly in many parts of the United States. A reservoir for the *A. phagocytophilum* in the eastern United States appears to be the white-footed mouse, *Peromyscus leucopus*, but increasing evidence also implicates deer or domestic ruminants. This suggests that efficient transmission requires persistent infection of mammals, long recognized in dogs with *E. canis*, ruminants with *A. phagocytophilum*, and other hosts of various ehrlichial species. However, while *E. chaffeensis* and *A. phagocytophilum* may cause persistent infections in animals, persistence is rarely proved in humans.

Pathogenesis.

Although patients with human monocytic ehrlichiosis and anaplasmosis often present with an illness that appears similar to RMSF or typhus, vasculitis is rare. Pathologic findings include diffuse but mild perivascular lymphohistiocytic infiltrates, infrequent hepatocyte apoptoses, Kupffer cell hyperplasia, mild lobular hepatitis, increases in mononuclear phagocyte infiltrates in the spleen, lymph nodes, and bone marrow in which occasional erythrophagocytic cells are present, granulomas of the liver and bone marrow in patients with *E. chaffeensis* infections, and hyperplasia of one or more bone marrow hematopoietic lineages.

The exact pathogenetic mechanisms are poorly understood, but histopathologic examinations suggest diffuse mononuclear phagocyte activation and overinduction of host immune and inflammatory reactions. This activation results in moderate to profound leukopenia and thrombocytopenia in the presence of a hypercellular bone marrow, and fatalities are often associated with severe hemorrhage or secondary opportunistic infections. Hepatic or other organ-specific injury occurs by an unknown mechanism that is apparently unrelated to direct infection. An unexplained observation in severe disease is the occurrence of diffuse alveolar damage that results in the clinical picture of adult respiratory distress syndrome (ARDS), which also appears to be unrelated to direct ehrlichial tissue damage. Meningoencephalitis with a mononuclear cell cerebrospinal fluid pleocytosis may be present in HME but is rare with anaplasmosis.

Clinical Manifestations.

HME, anaplasmosis, and ehrlichiosis ewingii are distinct clinical entities caused by infection with different species that result in similar illnesses. Many well-defined cases of pediatric infection of variable severity have been reported, including one fatality from HME and anaplasmosis each. Insufficient numbers of children infected with *E. ewingii* have been identified to allow a thorough characterization. The incubation period after the last preceding tick bite or tick exposure ranges

from 2 days to 3 wk. No tick bite is documented in nearly one fourth of all patients. The diseases usually present with nonspecific findings including fever and headache. A majority of patients also describe myalgias, anorexia, and nausea or vomiting. Unlike adult patients, nearly two thirds of children with HME present with a rash. The rash is usually described as macular or maculopapular, although petechial lesions may occur. Photophobia and conjunctivitis also may occur, and pharyngitis and lymphadenopathy are seen in a minority of patients.

Hepatomegaly and splenomegaly are frequent physical findings, and a systolic ejection murmur is often identified. Meningoencephalitis with a mononuclear cell-predominant cerebrospinal fluid pleocytosis is infrequently encountered but can be a severe complication in HME, but appears to be rare with anaplasmosis. The presence of arthritis or arthralgias may suggest Lyme borreliosis or meningococcemia, but this presentation appears to be infrequent. Edema of the face, hands, and feet may contribute to diagnostic uncertainty.

The illness ordinarily lasts 4–12 days, and in most published cases hospitalization was required. Well-documented cases of seroconversion in the absence of overt clinical manifestations strongly suggest the occurrence of mild or subclinical infections. Clinically evident infections of children with ehrlichiosis ewingii are infrequent; however, the clinical presentation of this illness in adults is very similar to that of adult *E. chaffeensis* infection.

Diagnosis.

As with RMSF, a delay in diagnosis or treatment may contribute to increased morbidity or mortality; thus, an early clinical diagnosis is important. Because both HME and anaplasmosis have been associated with a fatal outcome, therapy should not be withheld while awaiting confirmatory laboratory test results.

Characteristically, most children with monocytic ehrlichiosis present with leukopenia (58–72%), lymphopenia (75–78%), or thrombocytopenia (80–92%). Leukocytosis may also occur. Despite the presence of pancytopenia, examination usually reveals a cellular or reactive bone marrow in adults. Interestingly, granulomas and granulomatous inflammation are identified in nearly 75% of bone marrow specimens examined from patients with proven cases of *E. chaffeensis* infection, but this finding is not present in patients with anaplasmosis. Mild to severe hepatic injury is documented by the frequent (83–91%) finding of elevated transaminase levels. Hyponatremia is present in a minority of cases. Severely affected children may experience varying degrees of renal failure accompanied by elevated concentrations of serum creatinine and urea nitrogen. A clinical picture similar to that of disseminated intravascular coagulopathy with prolonged activated partial thromboplastin time and prothrombin time and hypofibrinogenemia has occurred in several patients.

The first patient and several subsequent pediatric patients with *E. chaffeensis* infection were identified presumptively on the basis of typical *Ehrlichia* morulae in peripheral blood leukocytes (Fig. 213–1*A*). This finding has been too infrequent to be considered a useful diagnostic tool. In contrast, anaplasmosis presents with a small but significant percentage (1–40%) of circulating neutrophils (see Fig. 213–1*B*) containing typical morulae in 20–60% of patients. The distinction between the two infections relies on polymerase chain reaction (PCR) amplification of species-specific DNA sequences or on the demonstration of specific antibodies to *E. chaffeensis* or *A. phagocytophilum* antigen.

The current diagnostic criteria for *E. chaffeensis* infection include a seroconversion with a titer of =1:64, or a single serum titer (usually convalescent serum) of =1:128, in the context of a clinically compatible illness. Similarly, anaplasmosis may be confirmed by a seroconversion or single high titer of *A. phagocytophilum* antibodies; some laboratories refer to the causative agent as the HGE agent or *E. equi*. *E. ewingii* infection induces antibodies that cross react with *E. chaffeensis* in routine serologic tests and can only be differentiated by identification of specific nucleic acids or by the demonstration of morulae in neutrophils where the *E. chaffeensis* titer is at least fourfold higher than the *A. phagocytophilum* titer. Patients with anaplasmosis experience serologic reactions to *E. chaffeensis* in up to 15% of cases, and thus serodiagnosis depends on testing with both *E. chaffeensis* and *A. phagocytophilum* antigens. During the acute phase of illness when antibodies may not be detected, PCR amplification of specific *E. chaffeensis* or *A. phagocytophilum* DNA sequences is sensitive in 50–86% of cases. *E. chaffeensis* and *A. phagocytophilum* have both been cultivated in tissue culture, but neither method provides a timely result.

DIFFERENTIAL DIAGNOSIS.

Because of the nonspecific presentation, ehrlichiosis may be mimicked by other arthropod-borne

Figure 213-1 Morulae in peripheral blood leukocytes in patients with HME and anaplasmosis. *A,* A morula *(arrow)* containing *Ehrlichia chaffeensis* in a monocyte. *B,* A morula *(arrowhead)* containing *Anaplasma phagocytophilum* in a neutrophil. Wright stains, original magnifications ×1,200. *Ehrlichia chaffeensis* and *A. phagocytophilum* have similar morphologies but are serologically and genetically distinct.

infections such as RMSF, tularemia, babesiosis, Lyme disease, murine typhus, relapsing fever, and Colorado tick fever. Other potential diagnoses considered include otitis media, streptococcal pharyngitis, infectious mononucleosis, Kawasaki disease, endocarditis, viral syndromes, hepatitis, leptospirosis, Q fever, collagen-vascular diseases, and leukemia. When rash and disseminated intravascular coagulopathy predominate, meningococcemia, bacterial sepsis, and toxic shock syndrome should be suspected. Meningoencephalitis may suggest enterovirus or herpes simplex virus infections, bacterial meningitis, or RMSF, whereas severe respiratory disease may be confused with bacterial, viral, or fungal pneumonitis.

Treatment.

Both ehrlichiosis and anaplasmosis are effectively treated with tetracyclines, especially doxycycline, and the majority of patients usually improve within 48?hr. In vitro tests document that both *E. chaffeensis* and *A. phagocytophilum* have chloramphenicol minimal inhibitory concentrations above safely achieved blood levels. Because of these findings, a short course of doxycycline is the recommended regimen. Doxycycline can be used safely in children <9 yr of age because tooth discoloration is dose dependent, and the need for multiple courses is unlikely. Little information exists to recommend alternative therapies; both *E. chaffeensis* and *A. phagocytophilum* are susceptible to rifampin in vitro, and it has been successfully used to treat anaplasmosis in pregnant women.

The recommended treatment regimen for patients with severe or complicated HME and anaplasmosis is doxycycline orally or intravenously (two loading doses of 2.2?mg/kg/dose q 12?hr followed by 2.2?mg/kg/24?hr divided q 12?hr PO or IV; maximum dose: 300?mg). The loading doses may be omitted in patients with less severe disease. An alternative regimen is tetracycline orally (25–50?mg/kg/24?hr divided q 6?hr PO; maximum: 2?g/24?hr). Therapy should be continued for a minimum of 5 days and until the patient has been afebrile for at least 2–4 days.

Other broad-spectrum antibiotics including penicillins, cephalosporins, aminoglycosides, and macrolides are not effective. *Anaplasma phagocytophilum* is not susceptible to azithromycin, but in vitro studies suggest a potential role for rifamycin in HME and anaplasmosis. In vitro studies show promising activity for quinolones against *A. phagocytophilum*; *E. chaffeensis* is naturally resistant. Increasing evidence suggests that the antecedent treatment with sulfamethoxazole-trimethoprim may result in more severe disease.

Complications.

Fatal monocytic ehrlichiosis has been reported in one pediatric patient where the findings were initially dominated by pulmonary involvement with respiratory failure complicated by nosocomial bacterial pneumonia. The pattern of severe pulmonary involvement culminating in diffuse alveolar damage and ARDS and secondary nosocomial or opportunistic infections is now well documented with HME and anaplasmosis in adults. One child with anaplasmosis died after a 3-wk interval of fever, thrombocytopenia, and lymphadenopathy suspected to be a hematologic malignancy. Other severe complications include a toxic shock–like illness, meningoencephalitis with long-term neurologic sequelae, brachial plexopathy, myocarditis, rhabdomyolysis, and renal failure. Patients with underlying immune compromise (e.g., HIV infection, high-dose corticosteroid therapy, cancer chemotherapy, organ transplantation) are at high risk for fulminant infection.

Prevention.

HME, anaplasmosis, and ehrlichiosis ewingii are tick-borne diseases, and any activity that allows exposure to the tick vectors increases risk. Avoidance of tick-infested areas, the wearing of appropriate light-colored clothing, tick repellents sprayed on clothing, careful inspection for ticks after exposure, and prompt removal of any attached ticks diminish the risk of acquisition of HME and anaplasmosis. The interval after tick attachment and before transmission of the infectious agents may be as short as 4?hr; thus, any attached tick should be promptly removed. The role of prophylactic therapy for ehrlichiosis and anaplasmosis after tick bites has not been investigated.

Chapter 214 - Q Fever (*Coxiella burnetii*)

Q fever (for query fever) is a febrile disease, often with no rash, that presents in acute and chronic forms.

Etiology.

The causative organism of Q fever, *Coxiella burnetii*, is genetically distinct from members of the genera *Rickettsia* and *Ehrlichia* and it is no longer classified within the order Rickettsiales, and has been assigned to the order Legionellales, family Coxiellaceae. *C. burnetii* is highly infectious for humans and animals; even a single organism can cause infection. The organism may enter a sporogenic differentiation cycle, unlike *Rickettsia*, which renders it highly resistant to chemical and physical treatments.

C. burnetii resides intracellularly within phagolysosomes. Unlike *Ehrlichia, Anaplasma*, and *Chlamydia, C. burnetii* tolerates and actively proliferates within the acidified phagolysosome to form aggregates that often contain >100 bacteria. *C. burnetii* organisms undergo a lipopolysaccharide “phase variation” similar to that described for smooth and rough strains of Enterobacteriaceae.

Epidemiology.

The disease is reported worldwide. Children younger than 19 yr and adults older than 80 yr are infrequently infected, most likely reflecting infrequent exposure. Serologic surveys in the United States and elsewhere indicate that many more cases of Q fever occur each year than are recognized, which is not surprising because acute Q fever is a nonspecific illness, specialized laboratory diagnostic tests are required, and it is not currently a notifiable disease in many states. *C. burnetii* may be the cause of 0.5–3% of serologically investigated acute respiratory illnesses or suspected viral hepatitis in some areas of the United States. In Japan and parts of Europe, *C. burnetii* is implicated as a cause of atypical pneumonia in up to 40% of pediatric patients. Immune compromise secondary to cancer therapies, AIDS, organ transplantation, hemodialysis, alcoholic liver disease, chronic granulomatous disease, or underlying cardiac valve or vascular damage or prostheses is identified as an underlying factor in >20% of patients with acute or chronic Q fever.

TRANSMISSION.

In contrast to other rickettsial infections, humans acquire *C. burnetii* predominantly after inhalation of infectious aerosols or by ingestion of contaminated foods; arthropod vectors are rarely implicated in human transmission. Domestic livestock (e.g., cattle, sheep, and goats), parturient cats, wild animals such as rabbits, and ticks serve as reservoirs. Frequent modes of transmission include aerosols from dust,

straw, cloth contaminated with organisms from birth tissues, or processing of animal products (in abattoirs, hides, wool), or by ingestion of contaminated raw dairy products (fresh cheese or unpasteurized milk). In Nova Scotia and Maine, exposure to newborn animals, chiefly kittens, has been associated with small outbreaks of Q fever in family settings. In Europe and Australia, exposure to domestic ruminants is the major risk; however, many urban dwellers in France, who presumably lack significant exposure to farm animals, acquire Q fever. Human placental infection is sometimes associated with intrauterine growth retardation or death and may result from primary or reactivation of maternal infection. Obstetric health care workers are at risk for acquiring infection because of the quantity of *C. burnetii* released from infected products of conception.

Pathogenesis.

The pathology of Q fever depends on the mode of transmission, the route of dissemination, and the specific tissues involved. After inhalation of infectious aerosols, pulmonary infection elicits a mild interstitial lymphocytic pneumonitis with a dense macrophage-rich intra-alveolar exudate that is heavily infected with *C. burnetii*. Single lesions may develop in the pulmonary parenchyma that histologically are inflammatory pseudotumors. Occasionally the characteristic fibrin-ring granulomas may be identified in liver, bone marrow, meninges, and other organs, and this finding is generally a sign of an acute, self-limited infection; with hepatic involvement, there is mild to moderate lymphocytic lobular hepatitis. Typically, infected tissues are moderately to densely infiltrated by lymphoid and histiocytic cells. Chronic Q fever endocarditis and prosthetic valve endocarditis is characterized by macrophage and lymphocyte-rich infiltrates in necrotic fibrinous valvular vegetations and by the absence of granulomas.

As with many other obligate intracellular pathogens, recovery from acute infection may result in nonsterile immunity and persistent subclinical infection. It is now recognized that development of chronic Q fever results after recovery from a mild or inapparent episode of acute Q fever, during which the agent is not cleared. The persistence of *C. burnetii* in tissue macrophages at sites of pre-existing tissue damage causes a low-grade smoldering inflammation, which eventually leads to irreversible cardiac valve damage or persistent vascular injury.

Clinical Manifestations.

Two forms of Q fever occur. The most frequent is acute Q fever, a self-limited form that is usually associated with an influenza-like illness and interstitial pneumonitis, granulomatous hepatitis, or both. Chronic Q fever usually implies involvement of the heart valves and often occurs in prosthetic valves or other endovascular prostheses;

it is diagnosed clinically as culture-negative endocarditis and often results in death.

ACUTE Q FEVER.

Acute Q fever develops about 3 wk (range, 14–39 days) after exposure to the causative agent. The severity of illness in children ranges from subclinical infection to a systemic febrile illness characterized by severe frontal headache, arthralgia, and myalgia, often accompanied by respiratory symptoms. Fewer than half of patients have cough or pneumonia. Most pediatric patients present with fever of unknown origin. In adults, the pneumonia usually resembles primary atypical or viral pneumonitis or legionnaires' disease with a nonproductive cough. Other prominent clinical findings that may lead to diagnostic confusion include fatigue, vomiting, abdominal pain, and meningismus. Hepatomegaly and splenomegaly may be detected in some patients.

In a review of 428 French patients with acute Q fever, 40% presented with hepatitis, 20% with hepatitis and pneumonia, 17% with pneumonia only, and 14% with isolated fever; other presentations included meningitis and meningoencephalitis, pericarditis, and myocarditis. Of those with either acute or chronic Q fever, 91% had fever, 34% had respiratory involvement, 11% had rash, and 4% had neurologic findings that required lumbar puncture for evaluation. Nearly 20% of patients with pneumonia alone were afebrile and such patients often present with one or more hepatic, pulmonic, cutaneous, or neurologic findings.

Laboratory investigations in acute Q fever are usually normal but may reveal leukopenia with a left shift (>5%) in 50% of patients and thrombocytopenia in 9–48%. Most children (62%) have elevated serum transaminase levels, which spontaneously return to normal after 20–30 days. The erythrocyte sedimentation rate is elevated in half of all Q fever cases. Chest X-ray films are abnormal in 27%, and pulmonary consolidations on radiographs become round and resolve slowly.

Acute Q fever in children is usually a self-limited illness that lasts 2–3 wk. However, severe infections including acute encephalopathy with impaired consciousness and an abnormal pattern on electroencephalogram and CT scans of the brain have been reported.

CHRONIC Q FEVER.

The risk of development of chronic Q fever is strongly correlated with advancing age and underlying conditions such as cardiac valve damage or immunosuppression. Thus, children are rarely diagnosed with chronic Q fever, including endocarditis. Chronic Q fever tends to be resistant to therapy and often results in death (23–65% of cases). Endocarditis, which almost invariably develops on damaged or prosthetic valves, may occur months to years after acute Q fever, or even in the absence of any history of acute Q fever. Less frequently, chronic Q fever may present as an infection of vascular prostheses and aneurysms, osteomyelitis, myocarditis, undifferentiated fever, pneumonia, and hepatitis, placental infection, or an isolated purpuric rash. The clinical presentation in children is similar to that in adults. In Q fever endocarditis, fever may be absent in up to 15% of cases, and more than 75% of all identified patients have congestive heart failure. Other frequently observed features include marked clubbing of the fingers, hepatomegaly, and splenomegaly.

Frequent laboratory abnormalities in patients with chronic Q fever include erythrocyte sedimentation rate >20?mm/hr (80% of cases), hypergammaglobulinemia (54%), and hyperfibrinogenemia (67%). The presence of rheumatoid factor in >50% of cases and circulating immune complexes in nearly 90%, plus the frequent findings of antiplatelet antibodies, anti–smooth muscle antibodies, antimitochondrial antibodies, circulating anticoagulants, and positive direct Coombs test results suggests an autoimmune process.

Diagnosis.

Although it is infrequently diagnosed, Q fever should be considered in children with fever of unknown origin, atypical pneumonia, or culture-negative endocarditis and who live in rural areas or who are in close contact with domestic livestock, cats, or animal products.

The diagnosis of Q fever is most easily confirmed serologically by testing acute and convalescent sera (2–4 wk apart), which show a fourfold increase in indirect fluorescent antibody titers to phase I and phase II antigens. Predominant, elevated, or increasing titers of phase II antibody are characteristic of acute Q fever, and the appearance and persistence of elevated titers of phase I and phase II antibody are indicative of chronic Q fever. Elevated titers of phase I immunoglobulin (Ig) A antibody are reported to be diagnostic for Q fever endocarditis; however, one evaluation showed that a phase II IgG titer of =1:200 is indicative of *C. burnetii* infection and that a phase I IgG titer of <1:800 is inconsistent with chronic Q fever.

C. burnetii has been cultivated in tissue culture cells, which may become positive within 48?hr, but isolation and antimicrobial susceptibility testing of *C. burnetii* should be attempted only in specialized biohazard facilities.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis depends on the clinical presentation. For respiratory disease, *Mycoplasma* pneumonia, legionellosis, psittacosis, and Epstein-Barr virus infection should be considered. For granulomatous

---

hepatitis, mycobacterial infections, salmonellosis, visceral leishmaniasis, toxoplasmosis, Hodgkin disease, ehrlichiosis, brucellosis, or autoimmune disorders including sarcoidosis should be considered. Culture-negative endocarditis also suggests infection with *Brucella* or *Bartonella*, or nonbacterial endocarditis.

Treatment.

Selection of an appropriate antimicrobial regimen for children is difficult owing to the lack of thorough studies, the limited therapeutic window for drugs that are known to be efficacious, and the potential length of therapy required to preclude relapse. Most

pediatric patients with Q fever experience a self-limited illness that is identified only on retrospective serologic evaluation. However, to prevent potential complications, patients with acute Q fever should be treated within 3 days of onset of symptoms with tetracycline (25–50?mg/kg/24?hr divided qid PO) or doxycycline (2.2?mg/kg/24?hr divided bid PO). Chloramphenicol is effective, but is unavailable as an oral preparation in the United States. Therapy started after 3 days of onset has little effect on the course of the acute infection. Because early laboratory confirmation is not currently available, empirical therapy is warranted in clinically suspected cases. The quinolones ofloxacin and pefloxacin have proved effective, and success with a combination of pefloxacin and rifampin has also been achieved with prolonged therapy (16–21 days). Macrolides, including erythromycin, clarithromycin, and roxithromycin, are less effective than doxycycline, but more effective than ß-lactams, which are ineffective. However, the efficacy of macrolides in children has not been well studied. Individual reports document success with a wide variety of agents including chloramphenicol, trimethoprim-sulfamethoxazole, and ceftriaxone. In anecdotal cases of hepatitis associated with "autoimmune" laboratory findings, prednisone was reported to provide additional clinical benefit.

For chronic Q fever, especially endocarditis, prolonged therapy is mandatory with the bacteriostatic drugs tetracycline or doxycycline in combination with bactericidal drugs such as rifampin, ofloxacin, or pefloxacin. The use of lysosomotropic alkalinizing agents such as chloroquine aids in maintaining the activity of pH-sensitive antimicrobial agents in the phagolysosomal environment of *C. burnetii*. The addition of hydroxychloroquine allowed a significant shortening of the interval for required therapy in a recent clinical study, and no patient treated for 18 mo with a combination of doxycycline and hydroxychloroquine developed relapse. For patients with heart failure, valve replacement may be warranted and should be accompanied by an effective antibiotic regimen to avoid reinfection of the prosthetic valves. Therapy should be monitored by periodic serologic evaluation; phase I titers of <1:200 for IgG and a negative IgA titer indicate cure. Even with such evaluation, cure of chronic Q fever in less than 2 yr is unlikely; thus, therapy should be continued for at least 18 mo. Interferon-? therapy has been used to control intractable Q fever endocarditis.

Prevention.

Recognition of the disease in livestock or other domestic animals should alert communities to the risk of human infection. Milk from infected herds must be pasteurized at temperatures sufficient to destroy *C. burnetii. C. burnetii* is resistant to significant environmental conditions but may be inactivated with a solution of 1% Lysol, 1% formaldehyde, or 5% hydrogen peroxide. Special isolation measures are not required because person-to-person transmission is rare, except during exposure to infected products of conception. A vaccine preparation is available and provides protection against Q fever for at least 5 yr in abattoir workers. Because the vaccine is strongly reactogenic and no trials in children have been conducted, it should only be used where extreme risk is judged to exist.

Section 10 - *Mycotic Infections*

Chapter 215 - *Candida*

Martin E. Weisse
Stephen C. Aronoff

Candidiasis is caused by several species of the genus *Candida*. The former genus name was *Monilia*, and the term **moniliasis** is still used occasionally to describe skin or mucous membrane infection. *Candida* exists in three morphologic forms: oval to round blastospores or yeast cells (3–6?mm in diameter); double-walled chlamydospores (7–17?mm in diameter), which are usually at the terminal end of a pseudohypha; and pseudomycelium, which is a mass of pseudohyphae and represents the tissue phase of *Candida*. Pseudohyphae are filamentous processes that elongate from the yeast cell without the cytoplasmic connection of a true hypha. *Candida* grows aerobically on routine laboratory media but may require several days for incubation.

C. albicans accounts for most human infections, but *C. parapsilosis*, *C. tropicalis*, *C. krusei*, *C. lusitaniae*, *C. glabrata* (formerly *Torulopsis glabrata*), and several other species have been reported as pathogens with increasing frequency. Because *C. albicans* is the most frequently isolated pathogen, a rapid **germ tube test** should be performed before further identification tests are ordered. *C. albicans* is the only species that forms a germ tube when suspended in rabbit or human serum and incubated for

1–2?hr. The other clinically important species can be identified within 48?hr on the basis of biochemical test results.

Treatment of invasive *Candida* infections has become complicated with the emergence of these non-*albicans* strains. Amphotericin is inactive against approximately 20% of strains of *C. lusitaniae*. Fluconazole is useful for many *Candida* infections but is inactive against all strains of *C. krusei* and approximately 20% of strains of *C. glabrata*. These species are usually susceptible to ketoconazole and itraconazole, but cross resistance to other azoles does occur. Susceptibility testing of these clinical isolates is recommended.

215.1 Neonatal Infections

Candida is a common cause of oral mucous membrane infections (thrush) and perineal skin infections (diaper dermatitis) in newborn infants. With the improved survival of very low-birthweight infants, disseminated *Candida* infections have become more frequent in special care nurseries; the incidence can be as high as 5% in very low-birthweight infants.

Epidemiology.

C. albicans is commonly part of the gastrointestinal and vaginal flora of adults. Pregnancy increases the rate of vaginal colonization from <20% to >30%. In approximately 10% of term infants, the gastrointestinal and respiratory tracts are colonized in the first 5 days of life; the colonization rate in infants weighing <1,500?g approaches 30%. Skin colonization is common after 2 wk of age. Neonatal risk factors for invasive candidiasis include prematurity, abdominal surgery, prolonged ventilatory support, prolonged intravenous catheterization, parenteral alimentation, and especially broad-spectrum antibiotic administration.

Pathogenesis.

The inability of the newborn infant to localize, control, and eradicate *Candida* infections appears to be related to the relative impairment of specific and nonspecific host defense mechanisms. Overgrowth of *Candida* on mucocutaneous surfaces and colonization of intravenous catheters favor entry and penetration; clinical infection is related to inoculum size. Hematogenous spread leads to vasculitis and miliary nodules in many organs. The liver, spleen, lungs, kidneys, gastrointestinal tract, heart, eyes, and meninges are commonly involved.

Clinical Manifestations.

The manifestations of systemic neonatal candidiasis vary in acuteness and severity, from thrush and candidal diaper dermatitis (see Section 215.2) to fungemia that may be asymptomatic or may be associated with sepsis and shock indistinguishable from bacterial sepsis. *Candida* causes significant disease in 2–5% of premature infants weighing <1,500?g. Cutaneous evidence of *Candida* infection is present in as many as half of these patients and manifests as a diffuse erythroderma or vesiculopustules from which the organism can be cultured. Renal involvement is found in >50% of patients and may be subclinical with persistent candiduria or may become manifest with a flank mass, hypertension, renal failure, renal abscesses, papillary necrosis, or fungal balls in the collecting system, resulting in obstruction and hydronephrosis.

Central nervous system involvement occurs in as many as one third of cases and

may involve the meninges, ventricles, or cerebral cortex with abscess formation. Clinical manifestations of central nervous system disease may be inapparent, which mandates evaluation of the cerebrospinal fluid in all neonates with disseminated candidiasis regardless of central nervous system signs or symptoms. Because endophthalmitis is seen in as many as 45% of cases, retinal examinations should be performed in neonates with systemic candidiasis; repeat examinations are necessary to monitor resolution of the retinal lesions. Endophthalmitis begins as chorioretinitis and may extend to the vitreous. Cotton ball exudates are typical of candidal retinal pathologic conditions. Osteoarthritis is a complication in 20% of cases.

Vascular disease ranges from vasculitis of the aorta or vena cava to endocarditis. Infected thrombi in vessels and the right atrium are not uncommon. Candidal endocarditis is an infrequent complication but should be considered in patients with central venous catheters that extend into the atrium as well as in those with persistent candidemia. Pneumonia occurs in as many as 70% of patients with disseminated candidemia on the basis of autopsy studies, although some patients do not have radiographic evidence of pneumonia on initial evaluation. Cultures from the endotracheal tube are not predictive of pulmonary involvement.

CONGENITAL CANDIDIASIS.

Congenital candidiasis, which is rare, occurs in otherwise normal neonates and presents at birth as widespread skin involvement, especially in the intertriginous areas. The pathogenesis of congenital candidiasis is ascending infection from a mother with heavy colonization or vulvar infection with *Candida*. The newborn rash is maculopapular; *Candida* may be recovered from some vesicles and pustules. There is usually little or no mucous membrane involvement. Topical antifungal therapy is usually all that is necessary unless the neonate shows evidence of systemic infection. Congenital candidiasis in preterm infants may progress to systemic disease.

Diagnosis.

Definitive diagnosis requires identification of the fungus histologically in tissue specimens or recovery of the fungus by culture of normally sterile body fluids. Buffy coat smears of blood may show yeast, allowing a preliminary diagnosis. Skin scrapings of generalized rashes in very low-birthweight infants with suspected systemic candidiasis should be examined microscopically for yeast. Because cultures of blood and cerebrospinal fluid are often intermittently positive, multiple samples should be obtained. Cerebrospinal fluid cultures are positive in one third of infants with disseminated infection. Cultures should be obtained from peripheral veins as well as catheters to differentiate systemic infection from contaminated catheters. *Candida* antigen detection from blood samples may increase detection of candidemia. Urine specimens for culture must also be obtained by catheterization or suprapubic tap to differentiate infection perineal colonization.

Radiographs of the chest may reveal pneumonia. Ultrasonography is useful for localizing *Candida* infection in the urinary tract, central nervous system, and cardiovascular system. Ultrasonography, CT, and MRI may also be helpful in identifying foci in the liver and spleen.

Treatment.

Transient candidemia and disseminated candidiasis may be associated with a contaminated intravascular catheter, which must be removed. Amphotericin B (0.5–1.0?mg/kg/24?hr IV) is the drug of choice for systemic candidiasis and is active against both yeast and mycelial forms. The duration of therapy varies widely according to the extent of infection, clinical response, and drug toxicity. The total recommended dose is 20–30?mg/kg. Nephrotoxicity is common in the newborn infant and generally presents with oliguria, azotemia, and hyperkalemia. Lipid-complex formulations of amphotericin B (5?mg/ kg/24?hr) are recommended for neonates with compromised renal function (including doubling of the serum creatinine with amphotericin B desoxycholate therapy), those who are receiving other nephrotoxic therapy, or those who are otherwise intolerant of amphotericin B desoxycholate. The addition of flucytosine (100–150?mg/kg/24?hr divided every 6?hr PO) is recommended for the treatment of central nervous system and parenchymal kidney infections. Patients must be observed for bone marrow, gastrointestinal, and hepatic toxicities.

Fluconazole has also been found to be useful for invasive neonatal *Candida* infections. It is inactive against all strains of *C. krusei* and approximately 20% of strains of *C. glabrata*. These are usually susceptible to ketoconazole and itraconazole, but cross resistance to other azoles does occur. The susceptibility of these clinical isolates should be tested if treatment with azoles is contemplated.

Vascular catheters associated with transient fungemia or disseminated infection should be removed, followed by treatment with amphotericin B for 2–3 wk. Infected intracardiac and intravascular thrombi usually must be resected, but resolution without surgery has been described.

215.2 Infections in Immunocompetent Children and Adolescents

Oral Candidiasis.

Oral thrush, or oral pseudomembranous candidiasis, is a superficial mucous membrane infection that affects approximately 2–5% of normal newborns. Infants acquire *Candida* from their mothers at delivery and remain colonized. Thrush may develop as early as 7–10 days of age. The use of antibiotics, especially in the 1st year of life, may lead to recurrent or persistent thrush. The plaques of thrush invade the mucosa superficially and may be found on the lips, buccal mucosa, tongue, and palate. Removal of plaques from these surfaces may cause mild punctate areas of bleeding, which helps to confirm the diagnosis. Thrush may be asymptomatic or may cause pain, fussiness, and decreased feeding. It is uncommon after 12 mo of age but may occur in older children treated with antibiotics. Persistent or recurrent thrush with no obvious predisposing reason, such as recent antibiotic treatment, warrants investigation of an underlying condition such as diabetes mellitus or

immunodeficiency, especially vertically transmitted HIV infection.

Treatment of mild cases may not be necessary. When treatment is warranted, the most commonly prescribed antifungal agent is nystatin. Therapeutic agents found to be effective include (in decreasing order of efficacy) miconazole gel, amphotericin B suspension, gentian violet, and nystatin suspension. Clotrimazole troches may also be effective, although clinical studies are lacking. Miconazole gel is currently unavailable in the United States. For recalcitrant or recurrent infections, a single dose of fluconazole may be useful. Fluconazole has been shown to be safe in premature infants, and effective in a single dose in HIV-infected children with oral candidiasis. In breast-fed infants, a single dose of fluconazole suspension by the mother may be adequate to treat both her and her infant.

Diaper Dermatitis.

Diaper dermatitis is the most common infection caused by *Candida*. Primary infection generally occurs in the intertriginous areas of the perineum and presents as a confluent papular erythema with erythematous satellite papules. *Candida* diaper dermatitis often complicates other noninfectious diaper dermatitides and occurs as an adverse effect of oral antibiotic treatment. Many physicians presumptively treat any diaper rash that has been present for >3 days for *Candida*.

Treatment is usually with nystatin cream, powder, or ointment; clotrimazole 1% cream; miconazole 2% ointment; or amphotericin cream or ointment. If significant inflammation is present, the addition of hydrocortisone 1% may be useful for the 1st day or two. Combination drugs with topical corticosteroids, such as clotrimazole/triamcinolone, should be used cautiously or not at all in infants because the relatively potent topical corticosteroid may lead to unwanted local adverse effects. Frequent diaper changes and short periods without diapers are important adjunctive treatments.

Periungual Infections.

Paronychia and onychomycosis may be due to *Candida*, although this agent is much less common than *Trichophyton* or *Epidermophyton* as a cause of periungual infection. Candidal onychomycosis differs from tinea infections by its propensity to involve the fingernails and not the toenails, and by the associated paronychia. Candidal infections often respond to treatment that consists of keeping the hands dry and using a topical antifungal agent. A short course of systemic therapy with an oral azole antifungal drug may be necessary.

Vulvovaginitis.

Vulvovaginitis is a common candidal infection of pubertal and postpubertal female patients that affects as many as 75% of female patients at one time or another (see Chapter 541). Predisposing factors include pregnancy, oral contraceptive use, poor hygiene, and use of oral antibiotics. Prepubertal girls with candidal vulvovaginitis usually have a predisposing factor such as diabetes mellitus or prolonged antibiotic treatment. Clinical manifestations may include pain or itching, dysuria, vulvar or vaginal erythema, an opaque white or cheesy exudate, and thrushlike mucosal plaques.

Candidal vulvovaginitis can be effectively treated with either vaginal creams or troches of nystatin, clotrimazole, or miconazole. Oral therapy with a single dose of fluconazole has been found to be as effective as topical clotrimazole in women. Persistent vulvovaginal candidiasis can be safely and effectively treated with fluconazole.

215.3 Infections in Immunocompromised Children and Adolescents

Etiology.

Most cases of candidemia in immunocompromised patients are due to *C. albicans* (70–90%). Other species commonly involved include *C. tropicalis* (5–15%), *C. parapsilosis* (3–13%), *C. glabrata* (0–4%), *C. lusitaniae*, *C. krusei*, and *C. guilliermondii* (all <2%).

Clinical Manifestations.

Candida infections in immunocompromised patients vary from superficial mucocutaneous infections to life-threatening sepsis and shock. Evidence of *Candida* of one organ system usually belies systemic infection and multiorgan involvement.

HIV-INFECTED CHILDREN.

Oral thrush and diaper dermatitis are the most common candidal infections in HIV-infected children, occurring in 50–85% of patients. Infants with symptomatic HIV infection are more than twice as likely to have thrush, which is often much more extensive in these infants than in healthy children. Besides oral candidiasis, three other clinical variants of candidal infection may be observed in HIV-infected children: **atrophic candidiasis,** which presents as a fiery erythema of the mucosa or loss of papilla of the tongue; **chronic hyperplastic candidiasis,** which presents with oral symmetric white plaques that cannot be rubbed away; and **angular cheilitis,** in which there is erythema and fissuring of the angles of the mouth. Topical therapy may be effective, but systemic treatment with fluconazole or itraconazole is usually necessary. Symptoms of dysphagia or poor oral intake may indicate that the infection has progressed to candidal esophagitis, necessitating systemic therapy with either itraconazole or fluconazole.

Candidal dermatitis and onychomycosis are also more common in HIV-infected children. These infections are generally more severe than they are in immunocompetent children and may require oral therapy or more aggressive and prolonged topical therapy.

CANCER AND TRANSPLANT PATIENTS.

Fungal infections, especially *Candida* and *Aspergillus* infections, are a significant problem in oncology patients with chemotherapy-associated neutropenia (see Chapter 164). Although the greatest risk for these patients is from bacterial

pathogens, the risk of candidemia increases dramatically after 5–7 days of neutropenia and fever. Accordingly, if fever and neutropenia persist for =5–7 days, amphotericin B is usually indicated because of the risk of systemic fungal infection. Fluconazole may be an acceptable alternative to amphotericin B for some patients in hospitals where drug-resistant *Candida* and *Aspergillus* species are uncommon.

Bone marrow transplant recipients have a much higher risk of fungal infection because of the dramatically increased duration

of neutropenia. Prophylactic use of fluconazole has been shown to decrease the incidence of candidemia in bone marrow transplant recipients but not in leukemia patients undergoing chemotherapy. An increased incidence of infection with *C. krusei*, which is resistant to fluconazole, has been noted. The use of myelopoietic colony-stimulating factor affects the duration of neutropenia after chemotherapy and is associated with decreased risk for candidemia. When *Candida* infection occurs, the lung, spleen, kidney, and liver are involved in >50% of cases.

Solid organ transplant recipients are also at increased risk for superficial and invasive candidal infections. Studies in liver transplant recipients demonstrate the utility of antifungal prophylaxis with either amphotericin B or fluconazole.

CATHETER-ASSOCIATED INFECTIONS.

Central venous catheter infections occur most often in oncology patients but may affect any patient with a central catheter (see Chapter 165). Neutropenia, use of broad-spectrum antibiotics, and parenteral alimentation are associated with increased risk of candidal central catheter infection. Recovery of *Candida* from the central catheter alone poses the same risk of disseminated infection as culture of the organism from both the central catheter and peripheral blood. Treatment requires removal of the catheter as well as a 2–3 wk course of amphotericin B (1?mg/kg/24?hr, total dose of 20?mg/kg).

Diagnosis.

Diagnosis may be presumptive in neutropenic patients with prolonged fever because positive blood fungal cultures occur only in a minority of patients who are later found to have disseminated infection. *Candida* grows readily on routine blood culture media; 90% or more of positive cultures are identified in 72?hr or less, and 97% or more are identified in 7 days or less. *Candida* recovered from urine or tracheal secretions may represent colonization or infection.

Treatment.

Amphotericin B remains the treatment of choice for systemic candidal infections, alone or with the addition of flucytosine or fluconazole, which is especially useful for central nervous system infections and parenchymal kidney infections. In one study in adults, fluconazole was as effective as amphotericin B for disseminated candidal infections and had fewer adverse effects. Fluconazole may be useful for selected candidal infections but is not effective against *C. krusei* and many strains of *C. glabrata*. Amphotericin is inactive against approximately 20% of strains of *C. lusitaniae*; susceptibility testing should be performed for all strains. Lipid-complex formulations of amphotericin B (5?mg/kg/24?hr) are recommended for persons with compromised renal function (including doubling of the serum creatinine with amphotericin B desoxycholate therapy), for those who are receiving other nephrotoxic therapy, or for those who are otherwise intolerant of amphotericin B desoxycholate.

215.4 Chronic Mucocutaneous Candidiasis

Chronic mucocutaneous candidiasis is a heterogeneous group of immune disorders, all of which involve a primary defect of T-lymphocyte responsiveness to *Candida*. Endocrinopathies (e.g., hypoparathyroidism, Addison disease) and autoimmune disorders are often associated with this disorder. Symptoms may begin in the first few months of life or as late as the 2nd decade of life. The disorder is characterized by chronic and severe skin and mucous membrane infections with *Candida* and occasionally other dermatophytes. Systemic candidiasis rarely occurs. Topical antifungal therapy may provide limited improvement early in the course of the disease, but repeated courses of ketoconazole or fluconazole, and occasionally amphotericin B, are usually necessary. The infection usually responds temporarily to treatment but is not eradicated and recurs.

Chapter 216 - *Cryptococcus neoformans*

Stephen C. Aronoff

Etiology.

Cryptococcosis is an invasive fungal disease caused by the monomorphic, encapsulated yeast *Cryptococcus neoformans. C. neoformans* var. *neoformans* predominates in temperate climates and is found in soil contaminated with avian droppings, on fruits and vegetables, and may be carried by cockroaches. It is the predominant pathogenic fungal infection among individuals infected with HIV. *C. neoformans* var. *gatti* is found mostly in the tropics under flowering river red gum trees *(Eucalyptus camaldulensis)* and causes endemic disease in the tropics in non–HIV-infected individuals. *C. albidus* and *C. laurentii* are rare human pathogens.

Epidemiology.

Cryptococcosis is an unusual disease in immunocompetent persons and is rare in children. Pigeon breeders and laboratory personnel who work with *Cryptococcus* are at greatest risk. Studies of cryptococcal seroprevalence show no evidence of exposure in young infants, <5% in children older than 5 yr of age, and 60% in adults. Cryptococcosis is also rare (<1%) among HIV-infected children but occurs in 5–10% of HIV-infected adults; higher rates of infection have been reported from developing countries. Pediatric cases of cryptococcosis are evenly divided among immunocompetent and immunocompromised individuals.

Pathogenesis.

In most cases *C. neoformans* is acquired by inhalation of fungal spores. Local inoculation rarely manifests into cutaneous or ophthalmic infection. Infection in immunocompetent persons is limited to the lung. When the immune system fails to contain the infection, dissemination follows with potential involvement of the brain, meninges, skin, eyes, and skeletal system.

Pulmonary cryptococcosis produces granulomas that are often subpleural in location and contain yeast forms. Cystic cryptococcomas occur in the central nervous system (CNS) in 20% of non–HIV-infected patients with disseminated disease and may be found in the absence of overt meningitis. Granulomas and microabscesses

containing yeast occur in patients with cutaneous and bony infection.

Clinical Manifestations.

Pneumonia is the most common form of cryptococcosis. Other manifestations include disseminated disease that may be associated with a sepsis syndrome, or focal symptoms such as meningitis, cutaneous infection, osteoarticular infection, or ocular infection that result from dissemination.

PNEUMONIA.

Asymptomatic pulmonary infections occur frequently, especially among pigeon breeders, bird fanciers, and microbiology laboratory workers. Asymptomatic carriage may occur in patients with underlying chronic lung disease. Progressive pulmonary disease is symptomatic and often precedes disseminated infection in the immunocompromised host. Fever, cough, pleuritic chest pain, and constitutional symptoms occur. Chest radiographs may demonstrate a poorly localized bronchopneumonia, nodular changes, or lobar consolidations; cavities and pleural effusions are rare.

DISSEMINATED INFECTION.

Disseminated infection follows primary pulmonary disease and occurs most often in immunocompromised individuals. HIV infection is the most common predisposing factor for disseminated cryptococcosis; other major predisposing conditions include hematologic malignancies, bone marrow transplantation, primary immunodeficiencies affecting both T- and B-cell lines, immunosuppression for rheumatic diseases, and celiac disease. A sepsis syndrome is a rare but often fatal manifestation of cryptococcosis that occurs almost exclusively in HIV-infected patients. Fever is followed by respiratory distress and multiorgan system disease.

MENINGITIS.

Subacute or chronic meningitis is the most common clinical manifestation of disseminated cryptococcal infection. The clinical presentation is variable and prognostic. Good outcomes are associated with headache as the initial symptom, normal mental status, absence of a predisposing condition, normal cerebrospinal fluid (CSF) opening pressure, normal CSF glucose, CSF leukocyte count of <20 cells/µL, negative CSF India ink stain, absence of extraneural infection by culture, and cryptococcal antigen titers in CSF and serum of <1:32. Overt symptoms of meningitis and HIV infection are predictors of a poor outcome. HIV-infected patients typically present with unexplained fevers, headache, and malaise with cryptococcal antigen titers >1:1,024. CT of the brain identifies cryptococcomas in as many as 30% of patients with disseminated infection and no clinical signs of CNS involvement. The mortality rate for cryptococcal meningitis is 15–30%, with most deaths occurring within several weeks of diagnosis. The fatality rates are higher in HIV-infected individuals, who have relapse rates of >50%. Relapse is unusual in adequately treated, non–HIV-infected patients. Postinfectious sequelae are common and include hydrocephalus, changes in visual acuity, deafness, cranial nerve palsies, seizures, and ataxia.

CUTANEOUS INFECTION.

Cutaneous disease may accompany disseminated cryptococcosis or local infection. Early lesions are erythematous, may be single or multiple, and are variably indurated and tender. Lesions often become ulcerated with central necrosis and raised borders. Cutaneous cryptococcosis in HIV-infected patients may resemble molluscum contagiosum.

OSTEOARTICULAR INFECTION.

Osteoarticular infection occurs in approximately 5% of individuals with disseminated infection but rarely in HIV-infected patients. The onset of symptoms is insidious and chronic. Bony involvement is typified by soft tissue swelling and tenderness, and arthritis is characterized by effusion, erythema, and pain on motion. Skeletal disease is unifocal in approximately 75% of cases. The vertebrae are the most common sites of infection followed by the tibia, ileum, rib, femur, and humerus. Concomitant bone and joint disease results from contiguous spread.

OCULAR INFECTION.

Chorioretinitis is rare, occurs primarily in adults, and is usually a manifestation of disseminated disease, although direct inoculation of the eye has been described. Eye infection is characterized by the acute loss of visual acuity, eye pain, visual floaters, and photophobia. On examination, choroiditis with or without retinitis is usually noted. Retinal and vitreal masses and anterior uveitis are seen less commonly. Because eye disease is often a manifestation of disseminated infection, the mortality rate with associated ocular infection is >20%. Only 15% of survivors recover full vision.

LYMPH NODES.

Lymphonodular disease has been reported in two children, one of whom had an underlying immunodeficiency. Lymphonodular cryptococcosis is characterized by disseminated lymphadenopathy including thoracic and abdominal nodes, subcutaneous lesions, liver granulomas, and concomitant pulmonary disease.

Diagnosis.

Definitive diagnosis requires identification of the fungus histologically in tissue specimens or recovery of the fungus from the site of infection by culture. A latex agglutination test, which detects cryptococcal antigen in serum and CSF, is the most useful diagnostic test. India ink preparations of CSF are useful prognostically but are less sensitive than culture and antigen detection. Skin test antigens are poorly characterized, and the sensitivity and specificity are unknown.

Immunocompetent persons with asymptomatic or mild disease limited to the lungs may be closely observed without therapy or, alternatively, treated with oral fluconazole (200–400?mg/24?hr) for 3–6 mo. All patients with cryptococcal antigen titers >1:8 should be treated. Immunocompetent hosts with progressive pulmonary disease or immunocompromised patients, other than HIV-infected persons, with disease limited to the lungs can be treated with amphotericin B (0.7–1?mg/kg/24?hr) alone or in combination with flucytosine. Lipid-complex formulations of amphotericin B (5?mg/kg/24?hr) are recommended for persons with compromised renal function (including doubling of the serum creatinine with amphotericin B desoxycholate therapy), for those who are receiving other nephrotoxic therapy, or for those who are otherwise intolerant of amphotericin B desoxycholate.

For the treatment of CNS and other manifestations of disseminated infection in non–HIV-infected individuals, staged therapy is often used. Initial treatment consists of amphotericin B (0.7–1?mg/kg/24?hr), or lipid-complex formulations of amphotericin B (5?mg/kg/24?hr), plus flucytosine (50–150?mg/kg/24?hr) for 2 wk; the dosage of flucytosine should be adjusted to maintain serum concentrations of 50–150?µg/mL. This regimen may be continued for a total of 6–10 wk, or fluconazole alone may be given orally for an additional 10 wk. Effectiveness of therapy is monitored by serial cryptococcal antigen testing; serum or CSF values of =1:8 are predictive of relapse. Ventriculoperitoneal shunts may be required for patients with hydrocephalus, and aggressive medical management of increased intracranial pressure may also be required.

Cryptococcosis in HIV-infected patients is prone to relapse upon termination of treatment. HIV-infected patients with isolated pulmonary disease require lifelong therapy with fluconazole. HIV-infected patients with CNS or disseminated cryptococcal infection require induction and maintenance therapy. Induction therapy consists of amphotericin B and flucytosine for at least 2 wk; amphotericin B may given alone if flucytosine is not tolerated. Amphotericin B and flucytosine may be continued for 6–10 wk as consolidation therapy, or fluconazole may be given alone for 10 wk. After completion of consolidation therapy, fluconazole is continued for life. Cessation of maintenance therapy for individuals whose HIV infection is well controlled on antiretroviral therapy has not been studied.

Cutaneous infections are usually treated medically, although surgical biopsy may be required for diagnosis. Skeletal infections generally require surgical debridement in addition to systemic antifungal therapy. Chorioretinitis also requires systemic antifungal therapy with amphotericin B and either fluconazole or flucytosine, both of which achieve high drug concentrations in the vitreous.

Chapter 217 - *Malassezia*

Martin E. Weisse

Members of the genus *Malassezia* include the causative agent of the fungal dermatosis tinea versicolor and have emerged as infrequent causes of fungemia in patients with indwelling catheters. *Malassezia* is a commensal lipophilic yeast with a predilection for the sebum-rich areas of skin. Because the yeast forms may be either oval or round, they were earlier designated *Pityrosporum ovale* and *P. orbiculare*. Transformation of the yeast to hyphal forms facilitates invasive disease. The clusters of thick-walled blastospores together with the hyphae produce the characteristic "spaghetti and meatballs" appearance. *M. furfur* is the most common clinical isolate of the seven species; however, *M. pachydermatis* has been implicated in several outbreaks in neonatal intensive care units.

M. globosa is a major cause of tinea versicolor (see Chapter 656). *Malassezia* has been implicated in neonatal acne and seborrheic dermatitis. *Malassezia* may be isolated from sebum-rich skin of asymptomatic persons, emphasizing that demonstration of the fungus does not equate with infection.

Catheter-related *Malassezia* fungemia occurs almost exclusively in patients receiving intravenous lipids. The use of lipid emulsions containing medium-chain triglycerides inhibits the growth of *Malassezia*, which may prevent infection with *Malassezia*. Infection is most common in premature infants, although immunocompromised patients, especially those with malignancies, may also be infected. Symptoms of catheter-associated fungemia are indistinguishable from other causes of catheter-associated infections (see Chapter 165) but should be suspected in patients, especially neonates, receiving intravenous lipid infusions. Compared with other causes of fungal sepsis, it is unusual for catheter-related *Malassezia* fungemia to be associated with secondary focal infection.

Malassezia does not grow readily on standard fungal media, and successful culture requires overlaying the agar with olive oil. Recovery of *Malassezia* from blood culture is optimized by supplementing the media with olive oil or palmitic acid.

Fungemia due to *M. furfur* or other species can be successfully treated in most cases by immediately discontinuing the lipid infusion and removing the infected catheter. For persistent or invasive infections, amphotericin B (desoxycholate or lipid-complex formulations), fluconazole, and itraconazole are effective. Flucytosine has no activity.

Chapter 218 - *Aspergillus*

Stephen C. Aronoff

Aspergillosis refers to a group of diseases caused by monomorphic, mycelial fungi of the genus *Aspergillus*. Most diseases in children are caused by *A. fumigatus* and less frequently by *A. flavus* and *A. niger*. Other species, including *A. nidulans* and *A. terreus*, have also been reported in pediatric infections. Aspergilli are distributed worldwide, and spores (conidia) are readily isolated from soil and decaying plants. Outbreaks of invasive disease among immunocompromised children may occur after they have been exposed to aerosolized conidia at construction sites within or near hospitals and clinics. Infection is usually acquired from inhalation of airborne spores, which colonize the upper and lower respiratory tracts. Immunocompromised persons are at risk for hematogenous dissemination. Cutaneous infection is also common and may follow wound contamination, intradermal inoculation, or hematogenous dissemination. Ingestion and aspiration may also produce disease. *Aspergillus*-associated diseases may be immunoglobulin (Ig) E mediated (hypersensitivity syndromes), saprophytic (noninvasive) syndromes, and invasive syndromes.

218.1 Hypersensitivity Syndromes

Asthma.

Atopic asthma (see Chapter 134) may be precipitated by inhalation of *Aspergillus* spores, which triggers an IgE-mediated response and bronchospasm. The clinical symptoms are nonspecific and include the acute onset of wheezing in the absence of pulmonary infiltrates or fever.

Extrinsic Alveolar Alveolitis.

Extrinsic alveolar alveolitis is a hypersensitivity pneumonitis that occurs in nonatopic individuals after repeated exposures to organic dust and usually with occupational exposure (malt worker's lung or farmer's lung). *Aspergillus* is one of many organic substances that produce this syndrome. The pathogenesis is unknown but is similar to the alveolitis caused by other immunogens and may represent an immune complex disease. The clinical manifestations typically follow exposure by 4–6?hr and include fever, cough, and dyspnea. Physical examination often reveals rhonchi without wheezes. Eosinophilia is absent from blood and sputum, and chest radiograph often shows diffuse interstitial infiltrates. Chronic exposure gradually leads to irreversible pulmonary fibrosis.

Allergic Bronchopulmonary Aspergillosis.

Allergic bronchopulmonary aspergillosis complicates chronic pulmonary disease in approximately 10% of children with asthma or cystic fibrosis. Chronic mucosal colonization with *A. fumigatus* produces an exaggerated IgG and IgE response, which results in recurrent bronchospasm and proximal cylindrical bronchiectasis. This should be considered in patients with asthma or cystic fibrosis who have recurrent bronchospasm and transient pulmonary infiltrates. Expectoration of mucous spirals containing mycelia is a hallmark of this illness; peripheral eosinophilia is common. Diagnostic criteria for allergic bronchopulmonary aspergillosis include (1) reversible paroxysmal bronchiolar obstruction (asthma); (2) immediate cutaneous reactivity to *A. fumigatus* antigens or specific serum IgE to *A. fumigatus*, by the radioallergosorbent test; (3) elevated total serum IgE; (4) peripheral blood eosinophilia; (5) precipitating serum antibodies against *A. fumigatus*; (6) history of previous pulmonary infiltrates; and (7) proximal bronchiectasis. The disease may progress through three stages: steroid responsive, steroid dependence, and end-stage pulmonary fibrosis.

Treatment.

Treatment of the hypersensitivity pulmonary syndromes focuses on anti-inflammatory agents, notably corticosteroids, and bronchodilator therapy. Acute exacerbations of disease are characterized by increased episodes of wheezing, diminished pulmonary function, and increased serum IgE concentrations. These episodes can be treated initially with prednisone 0.5?mg/kg/24?hr for 1 wk followed by 0.5?mg/kg every other day until symptoms abate and serum IgE returns to pre-illness levels. Although not studied in children, adults with allergic bronchopulmonary aspergillosis randomized to oral itraconazole for 16 wk experienced fewer symptoms, had reduced serum IgE concentrations, and required less prednisone than placebo recipients.

218.2 Saprophytic (Noninvasive) Syndromes

Otomycosis.

Otomycosis is a chronic condition that is found predominantly in tropical and subtropical regions and is rare in infants and children. Most infections are due to *A. niger* or, less commonly, *A. fumigatus*; co-infection with *Staphylococcus aureus* or *Pseudomonas* occurs in one third of cases. Most cases are unilateral, with presenting symptoms of ear pain, itching of the auditory canal, and a sense of fullness. Otorrhea, decreased hearing, and tinnitus are less common. Examination of the auditory canal typically shows conidial “forests” or mycelial mats. Topical antifungal agents such as nystatin, tolnaftate, dilute acetic acid, and corticosteroids

are therapeutic. Oral itraconazole has also been effective; however, experience is limited.

Sinus Disease.

Aspergillus noninvasive sinonasal disease may present in three forms. Chronic or indolent sinusitis is confined to one sinus and presents as a chronic sinus infection that is unresponsive to antibacterial therapy. Sinus radiographs are nonspecific, showing mucosal thickening without bony changes. Endoscopic surgery is curative in most cases. Sinus aspergilloma, which is rare in children, presents with long-standing nasal symptoms. Sinus radiographs demonstrate a solitary mass in the ethmoid or maxillary sinus. Bony destruction is variable. Surgical removal of the mass, which can often be performed endoscopically, is the treatment of choice. Allergic fungal sinusitis involves multiple sinuses and occurs in immunocompetent persons who usually have a history of multiple preceding sinus surgeries and nasal polyposis. *Aspergillus* and, less often, *Curvularia lunata* are the usual etiologic agents. Histology of nasal secretions in these patients reveals thick mucin, eosinophils, and few fungal hyphae. Sinus imaging typically shows involvement of multiple sinuses with hypodense areas and occasionally calcifications and bony erosions. Criteria for the diagnosis of allergic fungal sinusitis are immunologic and are identical to those listed for allergic bronchopulmonary aspergillosis, which may complicate allergic fungal sinusitis. Treatment includes surgical drainage and debridement as well as corticosteroid therapy. Antibiotics may be required for secondary bacterial infections.

Pulmonary Aspergilloma.

Pulmonary aspergillomas develop in poorly drained bronchi or pre-existing pulmonary cavities and may complicate pulmonary tuberculosis, histoplasmosis, blastomycosis, or sarcoidosis; rarely, aspergillomas complicate invasive *Aspergillus* pulmonary disease. Colonization and fungal proliferation occur in the cavity, but no vascular invasion occurs; an amorphous mycelial mass (mycetoma or fungus ball) results. Affected children are often asymptomatic or have cough and hemoptysis. Chest radiographs characteristically demonstrate the air shadow of a pulmonary cavity outlining a rounded mass; these findings may be confirmed by CT of the chest. Management is controversial and may range from watchful waiting for asymptomatic and otherwise healthy children to surgical resection for those patients with symptoms.

218.3 Invasive Disease

Pneumonia and Disseminated Infection.

Invasive pulmonary aspergillosis is the most common form of *Aspergillus* infection and usually occurs in immunocompromised patients. The onset is often insidious. In both immunocompetent and immunocompromised patients, symptomatic infection presents acutely with fever, cough, dyspnea, and abnormal chest findings; pleuritic chest pain is an infrequent complaint. Chest radiographs often show nodular infiltrates. Coexisting sinusitis is a common finding in neutropenic children. In children with chronic granulomatous disease, direct extension from the lungs to the chest wall has been reported.

The diagnosis is confirmed by histologic demonstration of hyphal invasion of blood vessels and recovery of the fungus by culture of the biopsy specimen. Recovery by culture or *Aspergillus* antigen detection in bronchoalveolar lavage fluid is also diagnostic in immunosuppressed patients with new pulmonary findings. Recovery of a pure culture of a single *Aspergillus* species in two sputum samples from immunocompromised patients with nodular, cavitary, or wedge-shaped lesions seen on chest radiographs is highly suggestive of invasive disease.

Treatment with high-dose amphotericin B (1?mg/kg/24?hr) for 4–6 wk, or until the neutropenia resolves or the underlying disease goes into remission, is recommended. Lipid-complex formulations of amphotericin B (5?mg/kg/24?hr) are recommended for persons with compromised renal function (including doubling of the serum creatinine with amphotericin B desoxycholate therapy), those who are receiving other nephrotoxic therapy, or those who are otherwise intolerant of amphotericin B desoxycholate. Completion of therapy with oral itraconazole has also been suggested but definitive trials are lacking.

Invasive *Aspergillus* infection is characterized by hyphal infiltration of vascular structures, thrombosis, and focal necrosis. Invasive disease occurs most commonly in immunocompromised patients, especially among patients with cancer who are receiving chemotherapy, HIV-infected persons, bone marrow transplant recipients, and, less commonly, solid organ recipients. Primary invasive disease may occur at any site in which airborne conidia may colonize and germinate, such as the respiratory tract or skin. In the severely neutropenic child, dissemination results from direct extension from the primary site and hematogenous seeding of distant sites. Sinonasal disease, pulmonary disease, and cutaneous disease are the most common primary infections in children. Otitis media is rare. Although systemic amphotericin B (either desoxycholate or lipid-complex formulations) remains the recommended treatment for most established *Aspergillus* infections, the outcome appears to hinge on resolution of the underlying immunocompromised state. Itraconazole, a triazole antifungal agent, has appreciable in vitro activity against *Aspergillus* but experience with this agent for the treatment of aspergillosis in children is limited. Aerosolized amphotericin B is currently under investigation for prophylaxis in cancer patients during periods of profound neutropenia.

Otitis Externa.

Otitis externa associated with *Aspergillus* infection is rare, occurs in immunosuppressed individuals, and is associated with hearing loss and direct extension to the petrous portion of the temporal bone and the pinna. Therapy includes surgical debridement and amphotericin B; experience with itraconazole is limited. Less invasive disease may be controlled with topical antifungal therapy, lavage, and cerumen removal.

Sinus Disease.

Acute, invasive sinusitis is rare in children and occurs almost exclusively in patients with profound neutropenia associated with chemotherapy for cancer. Fever, cough, epistaxis, headache, and sinus pain are the most common clinical signs.

Examination typically shows nasal crusting with rhinorrhea, sinus tenderness, nasal or oral ulceration, and duskiness or necrosis of the nasal septum or inferior turbinates. Multiple

sinus involvement with opacification or air-fluid levels can be demonstrated radiographically or by CT. Endoscopic examination demonstrates mucosal necrosis. Biopsy and culture of the nasal or sinus mucosa demonstrate large numbers of hyphae, and fungal cultures typically yield *A. fumigatus*, *A. flavus*, or, less often, *Rhizopus* or *Candida*. The disease is characterized by rapid spread to adjacent tissues and a high mortality rate. Treatment is not standardized but often includes surgical drainage, intravenous and intranasal amphotericin B, and removal of avascular necrotic tissue. Extensive surgical procedures are often hampered by underlying thrombocytopenia with extensive and at times life-threatening hemorrhage. Sporadic treatment successes and failures have been reported with itraconazole; however, comparative data with amphotericin B are not available. Invasive sinusitis has a poor prognosis for children with leukemia in relapse; better outcomes result from resolution of the granulocytopenia or remission of the underlying disease.

Chronic invasive sinus disease occurs in immunocompetent individuals who live in arid regions where endemic mold counts are high such as the Middle East and Africa. *A. flavus* is the most common pathogen. Infected patients have a progressive course spanning months to years, with extension of the infection to the surrounding sinuses, orbits, and cranial vaults. Treatment encompasses surgical debridement and drainage. Antifungal therapy is occasionally used.

Skin.

Cutaneous aspergillosis is a common manifestation of invasive aspergillosis in immunocompromised children. Cutaneous disease may result either from direct inoculation of the skin, typically at sites of local trauma such as intravenous catheter sites or complicating burn wounds or diaper dermatitis, or, more frequently, from hematogenous dissemination. The skin lesions appear initially as tender erythematous plaques that progress to hemorrhagic bullae and necrotic ulcers and eschars, termed ecthyma gangrenosum. Cutaneous aspergillosis in most children with profound neutropenia is a sentinel marker of disseminated *Aspergillus* disease and portends a poor outcome. Treatment with high-dose amphotericin B (1?mg/kg/24?hr) is recommended for 4–6 wk, or until the neutropenia resolves or the underlying disease is in remission. Lipid-complex formulations of amphotericin B (5?mg/kg/24?hr) are recommended for persons with compromised renal function (including doubling of the serum creatinine with amphotericin B desoxycholate therapy), for those who are receiving other nephrotoxic therapy, or for those who are otherwise intolerant of amphotericin B desoxycholate. Local debridement and topical amphotericin B have also been used. Experience with itraconazole is limited.

Onychomycosis due to *Aspergillus* may be treated successfully with oral itraconazole alone or combined with topical therapy.

Eye.

Fungal endophthalmitis is an important diagnostic finding in immunosuppressed children with disseminated *Aspergillus* infection. Although most patients have no ocular symptoms, pain, photophobia, and diminished visual acuity may occur. Examination of the retina shows focal retinitis, an overlying vitreitis, and retinal hemorrhage. Treatment of the underlying immunosuppressive illness, systemic antifungal therapy, vitrectomy, and intraocular amphotericin B are recommended. Amphotericin B and itraconazole achieve poor intraocular concentrations.

Orbital cellulitis rarely complicates invasive sinusitis and follows destruction of the orbital walls and fungal extension into the retro-orbital space. Diplopia, periorbital edema, proptosis, and pain on lateral gaze may occur. Treatment requires a combination of surgical debridement, systemic antifungal therapy, and resolution of the underlying immunocompromised state.

Fungal keratitis and episcleritis are rare and follow direct inoculation of spores into the eye. In the absence of disseminated disease, topical and intrascleral amphotericin B therapy is recommended.

Central Nervous System.

Cerebral aspergillosis is a rare and almost uniformly fatal complication of disseminated disease. In most cases, infection involves single or multiple foci within the cerebral hemispheres or cerebellum. Focal neurologic deficits begin acutely, most often hemiparesis, anterior cranial nerve palsies, or seizures; progression to herniation is rapid. Meningeal signs are rare. At autopsy arachnoiditis is limited to the area adjacent to the cerebral focus. Cerebrospinal fluid shows a mild mononuclear pleocytosis, elevated CSF protein, and variable degrees of hypoglycorrhachia. Imaging studies demonstrate focal central nervous system lesions with edema and variable enhancement. The diagnosis can be established by the acute appearance of neurologic symptoms in a patient with proven or suspected invasive aspergillosis or occasionally by cerebrospinal fluid or brain biopsy culture. High-dose amphotericin B combined with flucytosine has been effective in a paucity of cases. In recalcitrant cases, intraventricular therapy may also be required.

Epidural abscess is a rare complication of vertebral osteomyelitis caused by *Aspergillus* species. In two children with epidural abscess, vertebral osteomyelitis, and cord compression, surgical decompression and high-dose amphotericin B were curative.

Bone.

Aspergillosis of the bone is an extremely rare disease and follows direct extension of infection from a surgical or traumatic wound, or hematogenous seeding. Involvement of the vertebrae is most common. Osteomyelitis of the rib is rare but occurs in children with chronic granulomatous disease and often represents extension from a pulmonary focus. Surgical drainage is often required. Although definitive studies are not available, therapy with amphotericin B plus flucytosine has been used successfully despite the poor bone penetration of amphotericin B. Itraconazole

achieves good bone concentrations and has been used successfully.

Heart.

Endocarditis is a rare form of aspergillosis and can follow contamination at the time of surgery or implantation of a contaminated graft, or, uncommonly, it may be a manifestation of disseminated aspergillosis. High-dose amphotericin B therapy coupled with surgical removal of infected grafts or prostheses is recommended.

Chapter 219 - Histoplasmosis (*Histoplasma capsulatum*)

Stephen C. Aronoff

Etiology.

The etiologic agent of histoplasmosis, *Histoplasma capsulatum*, exhibits temperature dimorphism, existing as a mycelial form (mold) in nature at ambient temperatures (25°C–30°C) and as a yeast in human tissues (37°C).

Epidemiology.

The saprophytic form is found in soil throughout the midwestern United States, primarily along the Ohio and Mississippi rivers; sporadic cases of human and animal histoplasmosis have been reported from 31 of the 48 contiguous states. In parts of Kentucky and Tennessee, almost 90% of the population older than 20 yr of age have positive skin tests to histoplasmin.

H. capsulatum thrives in soil rich in nitrates such as areas that are heavily contaminated with bird droppings or decayed wood. Fungal spores are often carried on the wings of birds. Focal outbreaks of histoplasmosis have been reported after aerosolization of microconidia resulting from construction in areas previously occupied by starling roosts or chicken coops or by chopping decayed wood. Unlike birds, bats are actively infected with *Histoplasma*. Outbreaks of histoplasmosis have also been reported after intense exposure to bat guano in caves and along bridges frequented by bats.

Pathogenesis.

Human infection begins with inhalation of microconidia that reach the alveoli, germinate, and proliferate as yeast. The initial infection is a bronchopneumonia. As the initial pulmonary lesion matures, giant cells form, which are followed by formation of granuloma and central necrosis. At the time of spore germination, yeast cells gain

access to the reticuloendothelial system by way of the pulmonary lymphatic system and hilar lymph nodes. Dissemination with splenic involvement typically follows the primary pulmonary infection. The immune response follows in approximately 2 wk. The initial pulmonary lesion resolves within 2–4 mo but may undergo calcification resembling the Ghon complex of tuberculosis; alternatively, “buckshot” calcifications involving the lung and spleen may be seen. Unlike tuberculosis, reinfection with *H. capsulatum* occurs and may lead to exaggerated host immune responses in some cases.

Clinical Manifestations.

There are three forms of human histoplasmosis: acute pulmonary infection, chronic pulmonary histoplasmosis, and progressive disseminated histoplasmosis. **Acute pulmonary histoplasmosis** follows initial or recurrent respiratory exposure to microconidia. Most patients are asymptomatic. Symptomatic disease occurs more often in young children; in older individuals, symptoms follow exposure to large inocula in closed spaces (e.g., chicken coops, caves) or prolonged exposure (e.g., camping on contaminated soil, chopping decayed wood). The prodrome is nonspecific and usually consists of flulike symptoms: headache, fever, chest pain, and cough. Hepatosplenomegaly occurs more often in infants and young children. Symptomatic infections may be associated with significant respiratory distress and hypoxia and may require intubation, ventilation, and corticosteroid therapy. Acute pulmonary disease may also present with a prolonged illness (10 days to 3 wk) consisting of weight loss, dyspnea, high fever, asthenia, and fatigue. Approximately 10% of patients with acute pulmonary infection present with a sarcoid-like disease that includes arthritis or arthralgia, erythema nodosum, keratoconjunctivitis, iridocyclitis, and pericarditis. Most children with acute pulmonary disease have normal chest radiography findings. Individuals with symptomatic disease typically have a patchy bronchopneumonia; hilar lymphadenopathy is variably present. In young children, the pneumonia may coalesce. Focal or buckshot calcifications are convalescent findings in patients with acute pulmonary infection.

Exaggerated immune responses to fungal antigens within the lung parenchyma or hilar lymph nodes produce thoracic complications of acute pulmonary histoplasmosis. **Histoplasmomas** are fibroma-like lesions of parenchymal origin that are usually solitary, asymptomatic, and often concentrically calcified. Rarely, these lesions produce broncholithiasis associated with “stone spitting,” wheezing, and hemoptysis. In endemic regions, these lesions may mimic parenchymal tumors and are occasionally diagnosed at lung biopsy. **Mediastinal granulomas** form when reactive hilar lymph nodes coalesce and mat together. Although these lesions are usually asymptomatic, huge granulomas may compress the mediastinal structures, producing symptoms of esophageal, bronchial, or vena caval obstruction. Local extension and necrosis may produce pericarditis or pleural effusions. **Mediastinal fibrosis** is a rare complication of mediastinal granulomas and represents an uncontrolled fibrotic reaction arising from the hilar lymph nodes. Structures within the mediastinum become encased within a fibrotic mass, producing obstructive symptoms including superior vena cava syndrome, pulmonary venous obstruction with a mitral stenosis-like syndrome, and pulmonary artery obstruction with congestive heart failure. Dysphagia accompanies esophageal entrapment, and a syndrome of cough, wheeze, hemoptysis, and dyspnea accompanies bronchial obstruction.

Chronic pulmonary histoplasmosis is an opportunistic infection in adult patients with centrilobular emphysema. This entity is rare in children.

Progressive disseminated histoplasmosis is a disease that affects infants and immunocompromised individuals. Disseminated disease of infancy occurs almost exclusively in children younger than 2 yr of age and follows primary pulmonary infection. Fever is the most common finding and may last for weeks to months before the condition is diagnosed. The majority of patients have hepatosplenomegaly, anemia, and thrombocytopenia. Pneumonia and pancytopenia are variably present. In one series, half of the infected infants had transient T-cell deficiencies and many experienced a transient hyperglobulinemia. Although chest radiographs are normal in more than half of these children, the yeast can frequently be identified on bone marrow examination.

Children who are immunocompromised from cancer and chemotherapy, organ transplant, or HIV infection are at increased risk for disseminated histoplasmosis. In non–HIV-infected persons, disseminated disease presents with unexplained fevers, weight loss, lymphadenopathy, and interstitial pulmonary disease. Extrapulmonary infection is a characteristic of disseminated disease and may include destructive bony lesions, oropharyngeal ulcers, Addison's disease, meningitis, cutaneous infection, and endocarditis. Elevated liver function test results and high serum concentrations of angiotensin-converting enzyme may be observed.

Disseminated histoplasmosis with HIV infection is an AIDS-defining disease. Disseminated disease is often preceded or followed by another opportunistic infection in this patient population. HIV-infected individuals at greatest risk for acquiring disseminated histoplasmosis are those with a history of exposure to avian excreta or bat guano, no history of antiretroviral therapy, or no history of previous antifungal prophylaxis. Fever and weight loss occur in most individuals, with pulmonary disease occurring in most patients. Hepatosplenomegaly, lymphadenopathy, skin rashes, and meningoencephalitis are variably present. A sepsis-like syndrome has been identified in HIV-infected patients with disseminated histoplasmosis, which is characterized by the rapid onset of shock, multiorgan failure, and coagulopathy.

Diagnosis.

Recovery of *H. capsulatum* by culture differs with the form of infection. In immunocompetent hosts with symptomatic or asymptomatic acute pulmonary histoplasmosis, sputum cultures are variably positive; cultures of bronchoalveolar lavage fluid appear to have a slightly higher yield than sputa. Blood cultures are sterile in patients with acute pulmonary histoplasmosis. Cultures from any source are typically sterile in individuals with the sarcoid form of the disease. Yeast forms may be demonstrated histologically in tissues from patients with complicated forms of acute pulmonary disease (histoplasmoma, mediastinal granuloma, and mediastinal fibrosis). Sputum cultures are positive in 60% of adults with chronic pulmonary histoplasmosis. The yeast can be recovered from blood or bone

marrow in >90% of patients with progressive disseminated histoplasmosis.

Radioimmunoassay is the most widely available diagnostic study for detection of fungal antigen in patients with suspected progressive disseminated histoplasmosis. In HIV-infected patients as well as others at risk for disseminated disease, *Histoplasma*-associated antigen can be demonstrated in the serum or urine in >90% of cases. False-positive results may occur in individuals with blastomycosis, coccidioidomycosis, and paracoccidioidomycosis. Antigen detection by enzyme immunoassay has comparable sensitivity and improved specificity but limited availability. Sequential measurement of antigen in patients with disseminated disease is useful for monitoring response to therapy. Serum and urine from individuals with acute or chronic pulmonary infections are variably antigen positive.

Seroconversion continues to be useful for the diagnosis of acute pulmonary histoplasmosis, its complications, and chronic pulmonary disease. Serum antibody to yeast and mycelium-associated antigens is classically measured by complement fixation. Titers >1:8 are found in >80% of patients with histoplasmosis, and titers of =1:32 are considered significant for the diagnosis of recent infection. Complement fixation antibody titers are often not significant early in the infection and do not become positive until 4–6 wk after exposure. Complement fixation titers may be falsely positive in patients with other systemic mycoses and may be falsely negative in immunocompromised patients. Antibody detection by immunodiffusion is less sensitive than complement fixation and is used to confirm questionably positive complement fixation titers. Skin testing is useful only for epidemiologic studies because cutaneous reactivity is lifelong, and intradermal injection may elicit an immune response in otherwise seronegative individuals.

Treatment.

Antifungal therapy is not warranted for immunocompetent persons with asymptomatic or mildly symptomatic acute pulmonary histoplasmosis. Oral itraconazole should be considered in patients with acute pulmonary infections who fail to improve clinically over a 1-mo period. Individuals with primary or re-exposure to pulmonary histoplasmosis who become hypoxemic or require ventilatory support should receive amphotericin B desoxycholate (0.7?mg/kg/24?hr IV) or a lipid-complex amphotericin B (3–5?mg/kg/24?hr IV), until improved; continued therapy with oral itraconazole for a minimum of 12 wk is recommended. Lipid-complex formulations of amphotericin B are recommended for persons with compromised renal function (including doubling of the serum creatinine with amphotericin B desoxycholate therapy), those who are receiving other nephrotoxic therapy, or those who are otherwise intolerant of amphotericin B desoxycholate. Patients with severe obstructive symptoms caused by granulomatous mediastinal disease can be treated initially with amphotericin B and then switched to itraconazole, which is given for 6–12 mo. Milder mediastinal disease can be treated with oral itraconazole alone. Some experts recommend that surgery be reserved for those patients who fail to improve after 1 mo of intensive amphotericin B therapy. Sarcoid-like disease with or without pericarditis may be treated with nonsteroidal anti-inflammatory agents.

Amphotericin B continues to be the cornerstone of therapy for infants with progressive disseminated histoplasmosis. In one study, sequential therapy with amphotericin B and oral ketoconazole for 3 mo was curative in 88% of patients. Alternatively, amphotericin B may be given initially followed by oral itraconazole as maintenance therapy for 6–18 mo, with the duration based on serial *Histoplasma* antigen testing.

Relapses in HIV-infected individuals with progressive disseminated histoplasmosis are common. Currently, induction therapy with amphotericin B (total dose 10–15?mg/kg in children; >500?mg in adults) or lipid-complex formulations is recommended. Lifelong suppressive therapy with daily itraconazole (200?mg/24?hr in adults) is also required. For severely immunocompromised, HIV-infected children living in endemic regions, itraconazole (2–5?mg/kg every 12–24?hr) may be used for prophylaxis. Care must be taken to avoid interactions between antifungal azoles and protease inhibitors.

Chapter 220 - Blastomycosis (*Blastomyces dermatitidis*)

Robin B. Churchill
Stephen C. Aronoff

Etiology.

The etiologic agent of blastomycosis, *Blastomyces dermatitidis*, exhibits temperature dimorphism, existing as a mycelial form (mold) in nature at ambient temperatures (25°C–30°C) and as a thick-walled yeast in human tissues (37°C).

Epidemiology.

Blastomycosis is an uncommon fungal infection and among children is rare; children <15 yr of age constitute only 2–10% of reported cases. Sporadic infection in endemic regions accounts for the majority of cases. Blastomycosis occurs primarily in North America but has been encountered in Africa, India, the Middle East, Central America, and South America. The organism is found throughout the midwestern, south-central, and southeastern United States, especially along the Ohio and Mississippi River valleys and in the Great Lakes region. Although difficult to isolate from soil, *B. dermatitidis* has been recovered from earth enriched with organic material, particularly near waterways in endemic areas. Epidemics are unusual but have been described after excavation of contaminated soil in endemic regions. Individuals who spend large amounts of time in wooded areas within endemic regions, such as hunters or forestry workers, are at highest risk for infection.

Pathogenesis.

The pathogenesis of blastomycosis is similar to that of histoplasmosis. The primary site of infection is the lungs. Inhalation of spores results in alveolar inoculation and germination to yeast forms. Although pulmonary macrophages eliminate the majority of spores before infection occurs, those that survive produce pneumonitis and may disseminate hematogenously. The immune response to infection consists of neutrophil and macrophage migration into infected tissues. The resulting "pyogranulomatous" response with associated necrosis and subsequent fibrosis is

characteristic of the disease.

Clinical Manifestations.

The clinical spectrum of disease in human blastomycosis is diverse and ranges from asymptomatic infection to disseminated disease. Lack of an inexpensive, reliable screening test prevents identification of infection in most asymptomatic individuals. Nonspecific symptoms such as weight loss, unexplained fever, night sweats, and malaise may be the initial complaints in some patients. Acute pneumonia is the most common form of blastomycosis in both adults and children. Patients usually present with the acute onset of fever, chills, and productive cough, at times with hemoptysis. The most common radiographic findings of acute pulmonary blastomycosis are nonspecific lobar and segmental consolidation. Diffuse pulmonary disease associated with adult respiratory distress syndrome has been described in immunocompetent adults with acute pneumonia. Chronic pneumonia is characterized by several months of weight loss, cough, night sweats, and chest pain. Fever is typically low grade, and hemoptysis can occur. Patients with chronic pneumonia are more likely to have masslike lesions shown on chest radiograph, but diffuse miliary patterns may be present. Cavitary disease is an uncommon complication of this form of infection.

Extrapulmonary or disseminated disease occurs in immunocompromised persons and is usually preceded by pulmonary symptoms. Dissemination to almost any organ can occur but the most common sites are skin, bone, central nervous system (CNS), and genitourinary system. Cutaneous disease follows hematogenous or direct inoculation of the subcutaneous tissue and appears as either verrucous or ulcerative lesions. Osteomyelitis occurs in 25–50% of patients with extrapulmonary infections. The long bones, skull, vertebrae, and ribs are most commonly involved, but almost any bone can be affected. Involvement of the CNS occurs in 10% of patients with extrapulmonary infections and is typified by intracranial abscesses or, rarely, meningitis. Prostatitis and orchitis can occur in male patients but is unusual. Endometrial disease in female patients is sexually transmitted. Laryngeal blastomycosis generally follows primary infection of the upper airway and presents as a laryngeal mass. Fungal abscesses may form anywhere, including the heart and its surrounding structures, the orbit, and the sinuses.

Diagnosis.

Definitive diagnosis requires identification of the fungus histologically in tissue specimens or recovery of the fungus by culture. Serologic diagnosis using complement fixation or immunodiffusion is insensitive and is complicated by the high rate of cross reactivity with anti-*Histoplasma* antibody. Enzyme-linked immunosorbent assay is the most specific serologic test and has shown sensitivities of 80–88% and specificities of 98–100% in some studies. Although serologic tests can be used adjunctively to support clinical and other laboratory data, they should not be used to exclude infection or as a basis for the initiation of therapy. Skin testing is unreliable because reactivity wanes over time at an unpredictable rate.

Treatment.

Because uncomplicated pneumonia may resolve spontaneously, some patients can be carefully monitored without therapy. Patients should be thoroughly evaluated for extrapulmonary disease before deciding to withhold therapy.

Treatment is required for patients who are immunocompromised or have progressive pulmonary disease, CNS disease, or disseminated disease. Specific treatment regimens are based on the location, severity, and immune status of the patient. Itraconazole (200–400?mg/24?hr) or fluconazole (400–800?mg/ 24?hr) for =6 mo is recommended for adults with mild to moderate pulmonary disease without CNS involvement. Itraconazole (5–7?mg/kg/24?hr) has been used successfully to treat a small number of children with non–life-threatening infections. Amphotericin B (total dose: =30?mg/kg in children; 1.5–2.5?g in adults) remains the drug of choice for life-threatening and CNS infections for adults and children, as well as blastomycosis in pregnant women and immunocompromised persons. Lipid-complex formulations of amphotericin B (5?mg/kg/24?hr) are recommended for persons with compromised renal function (including doubling of the serum creatinine with amphotericin B desoxycholate therapy), those who are receiving other nephrotoxic therapy, or those who are otherwise intolerant of amphotericin B desoxycholate. Immunocompromised persons, especially patients with AIDS, may require chronic suppressive therapy after completion of a course of amphotericin B. In selected cases of pulmonary or extrapulmonary disease, initial therapy with amphotericin B can be switched to itraconazole or fluconazole after the patient's condition has stabilized. The role of surgery in the treatment of blastomycosis is limited.

Chapter 221 - Coccidioidomycosis (*Coccidioides immitis*)

Demosthenes Pappagianis

Etiology.

Coccidioidomycosis (San Joaquin fever, Valley fever, desert rheumatism, coccidioidal granuloma) is an infection caused by the fungus *Coccidioides immitis*, which is found in the soil. *C. immitis* exhibits dimorphism, existing as a filamentous mycelial form (mold) in nature and usual laboratory cultures; and, influenced by body temperature, leukocytes, increased CO_2 , and surface active substances, as an endosporulating spherule in human tissues.

Epidemiology.

C. immitis is concentrated in generally arid areas of the Western hemisphere, including California, Arizona, Texas, parts of Nevada, and Utah (including Dinosaur National Monument), Mexico, Central America, and South America (including Brazil). Longtime residents—humans, cattle, sheep, dogs, wild rodents, and other animals—have been infected; however, even transient visitors can develop the disease, which may not be considered in the differential diagnosis when they return to nonendemic areas. Many environmental influences affect the incidence of the disease. Recovery from infection generally confers permanent immunity.

Pathogenesis.

The minute arthroconidia of the *C. immitis* mycelial saprophytic phase that are airborne in dust are inhaled or, rarely, enter the host through injured skin. In the infected host they round up into spherules, which develop endospores. Liberation of the endospores leads to formation of new spherules and endospores, which spread within a host but not to a new host. Viable *C. immitis* occurs in pulmonary cavities, often in the mycelial as well as spherule form. However, person-to-person transmission of infection has been documented only through organ transplantation from an infected individual. The arthroconidia that occur in nature and on the surface of cultures are highly infectious. Although isolation of the patient is unnecessary, precautions should be taken with dressings and casts over open lesions to preclude the development of infective arthroconidia, which occurs in 4–5 days on surface cultures.

Clinical Manifestations.

Human infection takes three forms (Fig. 221–1): (1) a benign, self-limited, primary infection (60% of infected persons show no clinical manifestations); (2) residual pulmonary lesions; and (3) a rare, disseminating, sometimes fatal disease. The disease tends to be milder in children; however, in children requiring medical attention, dissemination to the bones and meninges is fairly common and approaches the incidence of these complications in adults. Laryngeal coccidioidomycosis, although not frequent, has been detected at a proportionately higher rate in children. Maternal-fetal and maternal-neonatal infections have been reported.

PRIMARY COCCIDIOIDOMYCOSIS.

The incubation period varies from 1–4 wk, with an average of 10–16 days. Symptoms are flulike; the onset may be insidious or abrupt with malaise, chills, and fever. Chest pain is frequent and may vary from a mere sense of constriction to excruciating pain. Night sweats and anorexia are common. On occasion, there is a persistent dry cough, and the throat may be painful. There also may be headache or backache.

An evanescent generalized, fine, macular erythema or urticarial eruption may appear within the 1st day or so and may be present only in the groin. Rarely, a varicella-like rash has been noted. Most frequently, tibial erythema nodosum occurs, with or without erythema multiforme, usually when sensitivity to coccidioidin is maximal from 3–21 days after onset of symptoms. These early rashes do not contain the organism and may result from hypersensitivity to coccidioidal antigen. Skin lesions may occur, however, in persons who are otherwise asymptomatic. Arthritis and phlyctenular conjunctivitis may occur concomitantly.

Auscultation of the lungs may be unrevealing, even though radiography reveals extensive consolidation. Dullness, a friction rub, or fine crackles may be detected. Pleural effusions occasionally occur, even without preceding respiratory symptoms, and may be sufficient to compromise respiratory status. Occasionally, acute respiratory insufficiency may occur.

RESIDUAL PULMONARY COCCIDIOIDOMYCOSIS.

A transient cavity may develop in an area of pulmonary consolidation during the primary infection. More often, however, after a variably prolonged period a persistent cavity may form, more often in patients with diabetes mellitus. There are often no symptoms, and the diagnosis is made radiographically. Occasionally, there is mild to moderate hemoptysis, which may recur and be alarming. Rarely, fatal hemorrhage occurs. Dissemination of the fungus from cavities to other areas is rare. Pulmonary residual “granulomas” sometimes persist. They are not harmful but are difficult to

differentiate from tuberculosis or neoplasms. Infrequently, a chronic progressive fibrocavitary pulmonary disease occurs.

DISSEMINATED OR PROGRESSIVE COCCIDIOIDOMYCOSIS (COCCIDIOIDAL GRANULOMA).

In certain persons, coccidioidal infection does not localize. Dissemination, which is rare and occurs mainly in male patients, especially Filipinos, other Asians, and blacks, usually follows the initial illness within 6 mo, often without any interlude. This is analogous to the course of progressive primary tuberculosis. Persons with blood group B and a certain class II human leukocyte antigen locus may

Figure 221-1 Natural history of coccidioidomycosis.

be particularly disposed to dissemination. Certain immunosuppressed states enhance dissemination or bring about relapse of apparently arrested coccidioidomycosis. Dissemination is likely if infection is acquired during pregnancy. Skin lesions and subcutaneous or osseous cold abscesses occur. Meningitis is the most serious of the disseminated lesions and is clinically similar to tuberculous meningitis. In whites, it is not unusual for meningitis to be the only extrapulmonary lesion. Miliary dissemination and peritonitis may be distinguishable from tuberculosis only by demonstration of the causative agent, although coccidioidal peritonitis may present as a very mild disease. The mortality rate of untreated meningitis is practically 100% but varies with other forms of disseminated coccidioidomycosis.

Diagnosis.

Disseminated infection may be established by biopsy or at autopsy. Sputum is often scanty with the primary infection; bronchoalveolar lavage or gastric aspirates, especially in children, may be advisable. The diagnosis is confirmed by detection of the characteristic double-contoured spherules with endospores, such as in an excised pulmonary nodule. Demonstration of the fungus by culture and confirmation by DNA probe, exoantigen test, or animal inoculation is also diagnostic. *Cultures are especially hazardous* and require special precautions.

The erythrocyte sedimentation rate is elevated in patients with primary or disseminated infection and is helpful in evaluating clinical status. Eosinophilia is common and is proportionately higher in patients with more severe infections. Serum alkaline phosphatase may be elevated in acute coccidioidomycosis even in the absence of obvious systemic dissemination.

The cerebrospinal fluid (CSF) findings in coccidioidal meningitis are similar to those of tuberculous meningitis (see Chapter 197). Eosinophilic pleocytosis may occur, and in rare instances CSF leukocytes have been reported as “malignant” cells. Lumbar puncture for CSF analysis should be performed in patients with disseminated or progressive coccidioidomycosis. Concomitant coccidioidomycosis and tuberculosis can be confounding.

SKIN TEST.

Intradermal tests with coccidioidin or spherulin are specific except for occasional cross-reactions in patients with histoplasmosis and blastomycosis. A positive reaction does not distinguish between a recent and an old infection unless it has been preceded within a reasonably short time by a negative test result. However, *a negative skin test does not exclude coccidioidal infection.* The reaction generally reaches its peak at 36?hr and should be read at 24 and 48?hr. An area of induration >5?mm in diameter is positive. Patients with suspected coccidioidal erythema nodosum are likely to be hypersensitive and should receive the 1:1,000 dilution. Some patients with disseminated infections are anergic; even a 1:10 dilution of antigen may not elicit a reaction. There is no danger of disseminating or activating a coccidioidal infection by producing a strong coccidioidin reaction, although there may be a local or systemic reaction. Coccidioidin does not evoke antibodies in the human; therefore, the skin test may precede serologic tests. A negative skin test should not preclude serologic tests. A positive skin test in a healthy individual indicates resistance to reinfection with *C. immitis*.

SEROLOGY.

Antibodies to *C. immitis* are generally not demonstrable in persons with asymptomatic acute infections. Serum precipitins, which are immunoglobulin (Ig) M antibodies, and complement fixation (CF) antibodies, which are IgG antibodies, are detectable in early coccidioidomycosis and may persist in those with disseminated coccidioidomycosis. Higher CF antibody titers are generally associated with more severe infections. Rarely, serologic tests may be negative in patients with active coccidioidomycosis, especially if they are immunocompromised.

Antibodies detectable by CF do not pass the blood-brain barrier, although immunodiffusion and enzyme immunoassay may reveal presence of the IgG in CSF that is concentrated, and are found in cord blood at the same titer as in the mother's blood. Passively transferred antibody disappears from the infant within

6 mo. Coccidioidal serum precipitins (IgM) has been detected in some neonates of mothers with coccidioidomycosis when there has been no manifestation of disease in the infants.

C. immitis antibodies in CSF, which are detectable in 95% of patients with meningitis, are usually diagnostic, although they occasionally are present in patients with epidural coccidioidal lesions. CF antibody can be detected in cisternal and lumbar CSF but may be deceptively absent from the ventricular CSF.

RADIOGRAPHY.

During the primary infection, chest radiography may not reveal pulmonary changes. There may be single or multiple, sharply circumscribed or soft, feathery, small pulmonary densities or larger consolidated areas. Hilar lymphadenopathy is frequent. Miliary or reticulonodular lesions are prognostically unfavorable. Pulmonary cavities, which occur less frequently in children than in adults, tend to be thin-walled. Pleural effusions vary in extent. Osseous lesions are usually lytic and have a predilection for

cancellous bone and can be single or multiple.

Treatment.

Because most primary coccidioidal infections resolve spontaneously over a variable time period, they have historically been treated conservatively. The patient's activity and symptomatic measures are restricted until the erythrocyte sedimentation rate returns to normal, clinical and radiographic improvements are noted, and the serum CF (IgG) antibody titer decreases. With the advent of the relatively benign oral azoles, physicians have often initiated therapy as soon as coccidioidomycosis is suspected or confirmed. There is limited evidence that such treatment for primary coccidioidomycosis hastens recovery or decreases the risk of extrapulmonary dissemination or development of pulmonary residua (e.g., cavity or solitary nodule).

Antifungal chemotherapy is indicated for those at high risk of severe coccidioidomycosis and those who have recognized metapulmonary dissemination. Currently available chemotherapeutic agents include oral fluconazole, oral or intravenous itraconazole, and oral ketoconazole, as well as amphotericin B, both desoxycholate and lipid-complex formulations. Indications for the choice of medication are not clearly defined. Amphotericin B (up to 1?mg/kg/24?hr) should be administered for rapidly progressing coccidioidomycosis. Lipid-complex formulations of amphotericin B (5?mg/kg/24?hr) are recommended for persons with compromised renal function (including doubling of the serum creatinine resulting from amphotericin B desoxycholate therapy), those who are receiving other nephrotoxic therapy, or those who are otherwise intolerant of amphotericin B desoxycholate. Once the full dose has been achieved, it can be given every other day or 2–3 times a week to minimize renal toxicity.

Systemic amphotericin B desoxycholate does not cross the blood-brain barrier in therapeutic amounts for *C. immitis*, but it may mask the presence of meningitis. Intrathecal (cisternal or lumbar) or intraventricular administration of amphotericin B had been the mainstay of treatment of coccidioidal meningitis. However, both fluconazole and itraconazole have proved useful in the treatment of coccidioidal meningitis, although lifetime treatment may be required.

Ketoconazole (3–10?mg/kg/24?hr), fluconazole (3–12?mg/kg/ 24?hr), or itraconazole (3–6?mg/kg/24?hr) administered orally have been useful in treating disseminated coccidioidomycosis outside the central nervous system that is neither extensive nor progressing rapidly. The higher doses may be required for the treatment of meningitis. The azoles have increasingly been used to treat children as well as adults with coccidioidomycosis, but there is limited information about their long-term adverse effects in younger patients. While ketoconazole can cause hepatic dysfunction and inhibit testosterone synthesis in adults, these effects have not been adequately evaluated in children. Fluconazole is primarily excreted by the kidneys, and itraconazole is metabolized in the liver; these drugs do not significantly affect testosterone or adrenocorticoid synthesis. On the basis of limited experience, coccidioidomycosis in pregnant women should be treated with amphotericin B, which has no apparent adverse effect on the fetus. Until more data are available, azoles should not be given to pregnant patients. The duration of therapy required with the azoles has not been clearly defined and must be determined individually. Relapses have occurred in some patients after favorable clinical responses have been seen following therapy for longer than 1 yr.

SURGERY.

Chronic pulmonary coccidioidal disease, cavitary or fibrocavitary, has not been consistently improved by the azoles or by amphotericin B. Pulmonary cavities may close spontaneously and are often best left alone, but when a cavity persists or is located peripherally, or when there is recurrent bleeding or rupture of the cavity through the pleura, excision should be considered. Coccidioidal cavities that have a fluid level or that are accompanied by fever or hemoptysis should initially be treated with antibacterial antibiotics. Infrequently, bronchopleural fistulas or recurrent cavitation occurs as a surgical complication; rarely, dissemination may result. When thoracic surgery is required, perioperative intravenous therapy with amphotericin B may be desirable.

Surgical drainage of cold abscesses, removal of infected synovial membranes, and curettage or excision of osseous lesions is recommended for localized extrapulmonary coccidioidomycosis. Local as well as systemic administration of amphotericin B can be used to treat coccidioidal articular disease. Limited experience indicates that artificial joints may be used to replace infected joints as long as antifungal (triazole) chemotherapy continues.

Prevention.

Avoidance of exposure to the arthroconidia is the only means of preventing infection. Whole killed cell vaccine did not prevent coccidioidomycosis in humans.

Chapter 222 - *Paracoccidioides brasiliensis*

Robin B. Churchill
Stephen C. Aronoff

Etiology.

Paracoccidioidomycosis (South American blastomycosis, Brazilian blastomycosis, Lutz-Splendore-Almeida blastomycosis) is an uncommon fungal infection of Central and South America. The etiologic agent, *Paracoccidioides brasiliensis*, exhibits temperature dimorphism, existing as a mycelial form (mold) in

nature at ambient temperatures (25°C–30°C) and as a yeast in human tissues (37°C).

Epidemiology.

P. brasiliensis is ecologically unique to Central and South America. Endemic outbreaks occur mainly in the tropical rainforests of Brazil with scattered cases in Argentina, Colombia, and Venezuela. A recent epidemiologic study showed increased incidence in areas with moderately high altitude, high humidity, and high rainfall and where coffee and tobacco are grown. The most common route of infection is by inhalation of conidia. The disease is not usually thought to be contagious and person-to-person transmission has not been confirmed. No animal vectors have been described.

Clinical Manifestations.

There are two clinical forms of disease. The acute form is rare, occurs almost exclusively in children and persons with impaired host defense, and targets the reticuloendothelial system. Pulmonary symptoms may be absent, although chest radiographs often show patchy, confluent, or nodular densities. Patients typically present acutely with fever, malaise, wasting, lymphadenopathy, and abdominal enlargement from intra-abdominal lymphadenopathy and hepatomegaly or

splenomegaly, which are nearly constant features. Multiple areas of osteomyelitis, arthritis, and pericardial effusions can also occur. This form of the disease has a 25% mortality rate.

Adults with extensive exposure to soil, such as farmers, are most likely to develop the chronic form that presents initially with flulike symptoms, fever, and weight loss. Pulmonary infection with progressive dyspnea, cough, chest pain, and hemoptysis is most common. Findings on physical examination are scant, although chest radiographs may show infiltrates that are disproportionately greater than the clinical findings. Mucositis involving the mouth and its structures as well as the nose may become manifest with localized pain, change in voice, or dysphagia. Lesions may extend beyond the oral cavity onto the skin. Generalized lymphadenopathy, hepatosplenomegaly, and adrenal involvement leading to Addison's disease may also occur.

Diagnosis.

Definitive diagnosis requires identification of the fungus histologically in tissue specimens or recovery of the fungus by culture. Demonstration of the fungus by direct (potassium hydroxide) wet mount preparation of sputum, exudate, or pus can establish the diagnosis in a high percentage of cases. Histopathologic examination of biopsy materials using special fungal stains is another effective method of diagnosis. The fungus can be recovered by culture on Sabouraud-dextrose or yeast extract agar. Antibodies to *P. brasiliensis* can be demonstrated in the sera of most patients. Serial antibody titers and lymphocyte proliferative responses to fungal antigens are useful in monitoring the response to therapy. Skin testing with paracoccidioidin is not reliable, in that one third of patients with active disease have test results that are nonreactive. Newer diagnostic methods that may prove to be very useful include polymerase chain reaction detection techniques to detect the organism in tissues and capture enzyme-linked immunosorbent assay to detect organism-specific immunoglobulin E in serum.

Treatment.

Recent studies suggest that itraconazole (50–400?mg/24?hr) for a mean duration of 6 mo is the treatment of choice for paracoccidioidomycosis. Fluconazole has also been used but higher doses (600?mg/24?hr, or greater) and longer treatment periods are required. Amphotericin B (total dose 3–6?g for adults) is recommended in cases of disseminated disease and failure of other therapies. Lipid-complex formulations of amphotericin B (5?mg/kg/24?hr) are recommended for persons with compromised renal function (including doubling of the serum creatinine with amphotericin B desoxycholate therapy), for those who are receiving other nephrotoxic therapy, or for those who are otherwise intolerant of amphotericin B desoxycholate. In the past, therapy with sulfonamide compounds, including sulfadiazine, trimethoprim-sulfamethoxazole (TMP-SMZ), and dapsone, have been used. Sulfonamide therapy is inexpensive but the treatment course is prolonged, lasting months to years depending on the agent selected. Terbinafine, a broad-spectrum antifungal allylamine that has been used to treat a variety of fungal infections in patients of all ages, has also recently been reported as successful treatment for a case of paracoccidioidomycosis unresponsive to treatment with TMP-SMZ in an adult.

Chapter 223 - Sporotrichosis (*Sporothrix schenckii*)

Robin B. Churchill
Stephen C. Aronoff

Etiology.

The etiologic agent of sporotrichosis *Sporothrix schenckii* exhibits temperature dimorphism, existing as a mycelial form (mold) in nature at ambient temperatures (25°C–30°C) and as a yeast in human tissues (37°C).

Epidemiology.

Sporotrichosis is a rare fungal infection that occurs worldwide both sporadically and in outbreaks. *S. schenckii* is distributed worldwide, but most cases of sporotrichosis are reported from North and South America and Japan. Most cases in the United States occur in the Midwest, particularly in areas along the Mississippi and Missouri Rivers. The fungus occurs in decaying vegetation and has been isolated most commonly from sphagnum moss, rosebushes, barberry, straw, and some types of hay. Disease in humans usually follows cutaneous inoculation of the fungus into a minor wound. Transmission from bites and scratches of animals, most frequently cats and armadillos, has occurred. Sporotrichosis is an occupational disease among farmers, gardeners, veterinarians, and laboratory workers. Reports of human-to-human transmission are rare. Pulmonary infection may result from the inhalation of large numbers of spores. Disseminated infection is unusual but can occur in immunocompromised patients following ingestion or inhalation of spores.

Pathogenesis.

The cellular immune response to *S. schenckii* infection is both neutrophilic and monocytic. T-cell–mediated immunity appears to be important in limiting infection; antibody does not protect against infection. Histologically, noncaseating granulomas and microabscess formation are characteristic. Due to the paucity of organisms, it is usually difficult to demonstrate the fungi in biopsy specimens.

Clinical Manifestations.

Cutaneous sporotrichosis is the most common form of disease in all age groups.

may either be **lymphocutaneous** or **fixed cutaneous**. Lymphocutaneous sporotrichosis accounts for >75% of reported cases in children and follows traumatic subcutaneous inoculation. After a variable and often prolonged incubation period (1–12 wk), an isolated, painless erythematous papule develops at the inoculation site, which is usually on an extremity but may be on the face in children. The original papule enlarges and ulcerates. Although the infection may remain limited to the inoculation site (fixed cutaneous form), satellite lesions follow lymphangitic spread and cause **nodular angiitis** with multiple tender subcutaneous nodules tracking the lymphatic channels that drain the lesion. These secondary nodules are subcutaneous granulomas that adhere to the overlying skin and subsequently ulcerate. Sporotrichosis does not heal spontaneously, and these ulcerative lesions may persist for years if they are untreated. Systemic signs and symptoms are uncommon.

Extracutaneous sporotrichosis is rare in children; most cases are reported in adults with underlying medical conditions. The most common form of extracutaneous sporotrichosis involves infection of the bones and joints. Pulmonary sporotrichosis usually presents as a chronic pneumonitis that is similar to the presentation of pulmonary tuberculosis.

Diagnosis.

Definitive diagnosis requires identification of the fungus histologically in tissue specimens or recovery of the fungus from the site of infection by culture. Special histologic staining, such as periodic acid–Schiff and methenamine silver, is required to identify yeast forms in tissues. Despite special staining techniques, diagnostic yield from biopsy specimens is low due to the small number of organisms present in the tissues. In cases of disseminated disease, demonstration of serum antibody against *S. schenckii*–related antigens can be diagnostically useful. New techniques for rapid identification of dimorphic fungal pathogens using specific DNA probes have recently been introduced and may be useful in the future.

DIFFERENTIAL DIAGNOSIS.

Lymphocutaneous and cutaneous sporotrichosis must be differentiated from other causes of nodular lymphangitis including atypical mycobacterial infection, nocardiosis, leishmaniasis, tularemia, melioidosis, cutaneous anthrax, and other systemic mycoses including coccidioidomycosis.

Treatment.

Although comparative trials and extensive experience in children are not available, itraconazole is the recommended treatment of choice for infections outside the central nervous system. The usual dosage for children is 5?mg/kg/24?hr up to 100?mg/24?hr; the adult dosage is 100–200?mg daily. Alternatively, younger

children with only cutaneous disease may be treated with a saturated solution (1?g/mL) of potassium iodide (SSKI) given orally. The dose is started at 5–10 drops three times per day and gradually advanced to 25–40 drops three times per day for children or 40–50 drops three times per day for adolescents and adults. Associated adverse effects of anorexia, nausea, a metallic taste, and rash contribute to poor patient compliance and should be managed by temporary cessation of therapy and reinstitution at a lower dosage. Therapy is continued until the cutaneous lesions have resolved, which usually takes 6–12 wk. SSKI is not effective for other forms of sporotrichosis. Terbinafine, an allylamine, also has been used successfully to treat cutaneous sporotrichosis but further data are needed before it can be recommended. Amphotericin B is the treatment of choice for pulmonary infections, disseminated infections, and infections in immunocompromised persons. Central nervous system infections should be treated with amphotericin B in combination with flucytosine. Lipid-complex formulations of amphotericin B are recommended for persons with compromised renal function (including doubling of the serum creatinine with amphotericin B desoxycholate therapy), for those who are receiving other nephrotoxic therapy, or for those who are otherwise intolerant of amphotericin B desoxycholate. Surgical debridement has a role in the treatment of some cases of sporotrichosis, particularly in osteoarticular disease. Therapy with azoles or SSKI should not be used in pregnancy. Pregnant women with pulmonary or disseminated disease should be treated with amphotericin B; pregnant women with cutaneous disease can be treated with **hyperthermic treatment** in the form of hot compresses or a hand-held heating device applied 40–60?min/24?hr, or therapy can be delayed until after delivery. Dissemination to the fetus does not occur, nor is the disease worsened by pregnancy.

Chapter 224 - Zygomycosis

Robin B. Churchill
Stephen C. Aronoff

Etiology.

Zygomycosis (mucormycosis or phycomycosis) refers to a group of opportunistic fungal infections characterized by vascular invasion, thrombosis, and necrosis caused by dimorphic fungi of the order Mucorales, which is in the class Zygomycetes. Members of the genera *Absidia, Mucor, Rhizopus*, and *Rhizomucor* are the most common causative organisms; *Cunninghamella* and *Apophysomyces* are seen less frequently. These are saprobic and parasitic fungi that are ubiquitous in soil, decayed plant or animal matter, and may be found on moldy cheese, fruit, and bread.

Epidemiology.

Zygomycosis is primarily a disease of persons with altered host defenses associated with underlying conditions such as diabetes mellitus, hematologic malignancies, persistent acidosis, iron overload, corticosteroid therapy, organ transplantation, and, less frequently, AIDS. Cases occur predominately in developed countries, likely related to the concentration of severely immunocompromised patients. Infections in healthy children are extremely rare but have been reported after insect bites or penetrating injuries. Person-to-person spread does not occur.

Pathogenesis.

The primary mechanism of acquisition of Zygomycetes is inhalation of the spores from the environment. Percutaneous inoculation can lead to cutaneous and subcutaneous zygomycosis, and ingestion of contaminated food or drinks has been linked to gastrointestinal disease. Neutrophils appear to be the most important component of the immune response against these organisms, which may explain the predilection zygomycoses among patients with conditions associated with neutropenia or neutrophil dysfunction.

Clinical Manifestations.

Zygomycosis can occur as any of several clinical syndromes including sinusitis/rhinocerebral, pulmonary, gastrointestinal, cutaneous, and disseminated disease. Rhinocerebral and pulmonary disease are most common.

Rhinocerebral zygomycosis occurs primarily in individuals with diabetes mellitus and hematologic malignancies. Initial symptoms consistent with sinusitis such as headache, retro-orbital pain, fever, and nasal discharge are followed by signs of orbital involvement including periorbital edema, proptosis, ptosis, and

ophthalmoplegia. The nasal discharge is often dark and bloody; examination of the nasal mucosa reveals black, necrotic areas. Extension beyond the nasal cavity is common. Involved tissues become red, then violaceous, and finally black as vessel thrombosis and tissue necrosis occur. Destructive paranasal sinusitis with intracranial extension can be demonstrated by CT or MRI scanning. Brain abscesses can result from direct extension of rhinocerebral infection from the nasal cavity and sinuses, usually to the frontal or frontotemporal lobes, or from disseminated disease, which may involve the occipital lobe or brainstem.

Pulmonary zygomycosis usually occurs in severely immunocompromised patients and is characterized by fever, tachypnea, and productive cough with pleuritic chest pain and hemoptysis. Signs of consolidation are found on physical examination. Chest radiograph findings are nonspecific and may show parenchymal infiltrate, lobar consolidation, or a nodular mass.

Gastrointestinal zygomycosis may occur as a complication of disseminated disease or as an isolated intestinal infection associated with diabetic mellitus, immunosuppression, malnutrition, or prematurity. Abdominal pain and distention with hematemesis, hematochezia, or melena may be seen. Stomach or bowel wall perforation is not uncommon.

Cutaneous zygomycosis can complicate burns or surgical wounds. An outbreak among preterm infants followed the use of contaminated wooden tongue depressors to immobilize the extremities. Outbreaks have also been associated with contaminated elastic bandages. Infection presents as an erythematous papule that ulcerates, leaving a black necrotic center. The skin lesions are painful and usually associated with fever.

Disseminated disease manifests as involvement of two or more organs; pulmonary involvement is usually present, but any organ can be involved. This form of disease occurs in the most severely immunocompromised patients. Signs and symptoms may be nonspecific, and prognosis is generally poor.

Diagnosis.

Definitive diagnosis requires identification of the fungus histologically in tissue specimens or recovery of the fungus by culture. Demonstration of fungal elements

with fungal specific stains such as calcofluor white or Gomori methenamine silver is recommended. In lung biopsy specimens and other tissue samples stained with silver, Mucorales appear as thick-walled, aseptate, right angle–branched hyphae. By gastrointestinal endoscopy, the lesions appear as black ulcers with deep erythematous margins. Vascular invasion is a hallmark of the disease. These fungi may also be identified in secretions by suspending the clinical material in a solution of 20% potassium hydrochloride before microscopic examination is performed. The fungi may be grown on standard laboratory media from sputum, bronchoalveolar lavage fluid, skin lesions, or biopsy material. Serologic tests for detecting zygomycosis are not clinically useful. Diagnosis of disseminated zygomycosis using a polymerase chain reaction assay has been recently reported and may prove to be a useful adjunct to standard diagnostic techniques in the future.

Treatment.

The optimal therapy for zygomycosis in children has not been established. All forms of the disease can be aggressive and difficult to treat, with high fatality rates. Correction of the underlying disease, if possible, is an essential component of management. Successful outcomes have been reported with extensive surgical debridement and high-dose amphotericin B therapy (1–1.5?mg/kg/24?hr to a total dose of 70?mg/kg, or 3–4?g in adults). Isolated pulmonary and cutaneous disease has been successfully treated with lower dosages of amphotericin B (30?mg/kg total dose). Lipid-complex formulations of amphotericin B (5?mg/kg/24?hr) are recommended for persons with compromised renal function (including doubling of the serum creatinine with amphotericin B desoxycholate therapy), those who are receiving other nephrotoxic therapy, or those who are otherwise intolerant of amphotericin B desoxycholate. Additional therapies have included rifampin and flucytosine in combination with amphotericin B, and hyperbaric oxygen and granulocyte-macrophage colony-stimulating factor as adjunctive therapies.

Section 11 - *Viral Infections*

Chapter 225 - Measles

Yvonne Maldonado

Measles (**rubeola**) is an important childhood disease that was widespread in the United States but is now very infrequent. However, in developing countries, measles is still an important cause of childhood morbidity and mortality. It is an acute viral infection characterized by a final stage with a maculopapular rash erupting successively over the neck and face, trunk, arms, and legs, and accompanied by a high fever.

Etiology.

Measles virus, the cause of measles, is an RNA virus of the genus *Morbillivirus* in the family Paramyxoviridae. Only one serotype is known. During the prodromal period and for a short time after the rash appears, virus is shed in nasopharyngeal secretions, blood, and urine. Virus can remain viable for at least 34?hr at room temperature.

Epidemiology.

Measles is endemic throughout the world. In the past, epidemics tended to occur irregularly, appearing in the spring in large cities at 2–4-yr intervals as new groups of susceptible children were exposed. It is rarely subclinical. Prior to the use of measles vaccine, the peak incidence was among children 5–10 yr of age. Individuals born before 1957 are considered to have had natural infection and to be immune.

During the 1980s the incidence of measles in the United States rose, probably due to inadequate vaccination as well as vaccine failure. The reported numbers of measles cases dropped from 894,134 cases in 1941 by more than 99.7% to an all-time low of 80 cases in 2000, probably as a result of intensified efforts to ensure appropriate vaccination. Measles now occurs most often among unimmunized preschool-aged children, as occasional epidemics in high schools and colleges, and as imported cases. Because measles is still a common disease in many countries, infective persons entering this country may infect United States residents, and Americans traveling abroad risk exposure there. More than half of the 108 cases reported in 2001 in the United States were imported or due to exposure to imported cases.

The Pan American Health Organization had established the goal of eliminating measles from the Western hemisphere by the year 2000. Although that goal has not been met, efforts have achieved interruption of indigenous measles transmission. During 1990–2000, measles cases in the Western Hemisphere declined 99.3%, from approximately 250,000 to 1,754 cases annually (Fig. 225–1). The many similarities among the biologic features of measles and smallpox suggest the possibility that measles might be eradicated. These features are (1) a distinctive rash as a sentinel marker; (2) no animal reservoir; (3) no vector; (4) seasonal occurrence with disease-free periods; (5) no transmissible latent virus; (6) one serotype; and (7) an effective vaccine. A prevalence of greater than 90% immunization of infants has been shown to produce disease-free zones.

TRANSMISSION.

Measles is highly contagious; approximately 90% of susceptible household contacts acquire the disease. Maximal dissemination of virus occurs by droplet spray during the prodromal period (catarrhal stage). Transmission to susceptible contacts often occurs prior to diagnosis of the index case.

Infants acquire immunity transplacentally from mothers who have had measles or measles immunization. This immunity is usually complete for the first 4–6 mo of life and wanes at a variable rate. Although maternal antibody levels are generally undetectable in infants after 9 mo of age by the usual antibody tests performed, some protection persists that may interfere with immunization administered before 12 mo of age. Most women of childbearing age in the United States now have measles immunity by means of immunization rather than disease, and studies suggest that infants of mothers with measles vaccine–induced immunity lose passive antibody at a younger age than infants of mothers who had measles infection. Infants of mothers who are susceptible to measles have no measles

Figure 225-1 Reported cases of measles and percentage of routine measles vaccination coverage among infants in North, Central, and South America (combined) from 1990 to 2001. (From Centers for Disease Control and Prevention: Progress toward interrupting indigenous measles transmission—Region of the Americas, January–November 2001. *MMWR* 2001; 50:1133–7.)

immunity and may contract the disease simultaneously with the mother before or after delivery.

Pathogenesis.

The essential lesion of measles is found in the skin, conjunctivae, and the mucous

membranes of the nasopharynx, bronchi, and intestinal tract. Serous exudate and proliferation of mononuclear cells and a few polymorphonuclear cells occur around the capillaries. Hyperplasia of lymphoid tissue usually occurs, particularly in the appendix, where multinucleated giant cells of up to 100?µm in diameter (**Warthin-Finkeldey reticuloendothelial giant cells**) may be found. In the skin, the reaction is particularly notable about the sebaceous glands and hair follicles. **Koplik spots** consist of serous exudate and proliferation of endothelial cells similar to those in the skin lesions. A general inflammatory reaction of the buccal and pharyngeal mucosa extends into the lymphoid tissue and the tracheobronchial mucous membrane. Interstitial pneumonitis resulting from measles virus takes the form of **Hecht giant cell pneumonia**. Bronchopneumonia may occur from secondary bacterial infection. In fatal cases of encephalomyelitis, perivascular demyelinization occurs in areas of the brain and spinal cord. In subacute sclerosing panencephalitis (SSPE), there may be degeneration of the cortex and white matter with intranuclear and intracytoplasmic inclusion bodies (see Chapter 225.1).

Clinical Manifestations.

Measles has three clinical stages: an incubation stage, a prodromal stage with an enanthem (Koplik spots) and mild symptoms, and a final stage with a maculopapular rash accompanied by high fever. The incubation period lasts approximately 10–12 days to the first prodromal symptoms and another 2–4 days to the appearance of the rash; rarely, it may be as short as 6–10 days. Body temperature may increase slightly 9–10 days from the date of infection and then subside for 24?hr or so. The patient may transmit the virus by the 9th–10th day after exposure and occasionally as early as the 7th day, before the illness can be diagnosed.

The prodromal phase usually lasts 3–5 days and is characterized by a low-grade to moderate fever, a dry cough, coryza, and conjunctivitis. These symptoms nearly always precede the appearance of Koplik spots, the pathognomonic sign of measles, by 2–3 days. An enanthem or red mottling is usually present on the hard and soft palates. **Koplik spots** are grayish white dots, usually as small as grains of sand, that have slight, reddish areolae; occasionally they are hemorrhagic. They tend to occur opposite the lower molars but may spread irregularly over the rest of the buccal mucosa. Rarely they are found within the midportion of the lower lip, on the palate, and on the lacrimal caruncle. They appear and disappear rapidly, usually within

12–18?hr. As they fade, a red, spotty discoloration of the mucosa may remain. The conjunctival inflammation and photophobia may suggest measles before Koplik spots appear. In particular, a transverse line of conjunctival inflammation, sharply demarcated along the eyelid margin, may be of diagnostic assistance in the prodromal stage. As the entire conjunctiva becomes involved, the line disappears.

Occasionally, the prodromal phase may be severe, being ushered in by a sudden high fever, sometimes with convulsions and even pneumonia. Usually the coryza, fever, and cough are increasingly severe up to the time the rash has covered the body.

The temperature rises abruptly as the rash appears and often reaches 40°C (104°F) or higher. In uncomplicated cases, as the rash appears on the legs and feet, the symptoms subside rapidly within about 2 days, usually with an abrupt drop in temperature to normal. Patients up to this point may appear desperately ill, but within 24?hr after the temperature drops, they appear well.

The rash usually starts as faint macules on the upper lateral parts of the neck, behind the ears, along the hairline, and on the posterior parts of the cheek. The individual lesions become increasingly maculopapular as the rash spreads rapidly over the entire face, neck, upper arms, and upper part of the chest within approximately the first 24?hr (Fig. 225–2). During the succeeding 24?hr the rash spreads over the back, abdomen, entire arm, and thighs. As it finally reaches the feet on the 2nd–3rd day, it begins to fade on the face. The rash fades downward in the same sequence in which it appeared. The severity of the disease is directly related to the extent and confluence of the rash. In mild measles the rash tends not to be confluent, and in very mild cases there are few, if any, lesions on the legs. In severe cases the rash is confluent, the skin is completely covered, including the palms and soles, and the face is swollen and disfigured.

The rash is often slightly hemorrhagic; in severe cases with a confluent rash, petechiae may be present in large numbers, and there may be extensive ecchymoses. Itching is generally slight. As the rash fades, branny desquamation and brownish discoloration occur and then disappear within 7–10 days.

The appearance of the rash may vary markedly. Infrequently a slight urticarial, faint macular, or scarlatiniform rash may appear during the early prodromal stage, disappearing in advance of the typical rash. Complete absence of rash is rare except in patients who have received immunoglobulin (Ig) during the incubation period, in some patients with HIV infection, and occasionally in infants younger than 9 mo of age who have appreciable levels of maternal antibody. In the hemorrhagic type of measles (**black measles**), bleeding may occur from the mouth, nose, or bowel. In mild cases the rash may be less macular and more nearly pinpoint, somewhat resembling that of scarlet fever or rubella.

Lymph nodes at the angle of the jaw and in the posterior cervical region are usually enlarged, and slight splenomegaly may be noted. Mesenteric lymphadenopathy may cause abdominal pain. Characteristic pathologic changes of measles in the mucosa of the appendix may cause obliteration of the lumen

Figure 225-2 Maculopapular rash of measles. (From Korting GW: *Hautkrankheiten bei Kindern und Jugendlichen*, 3rd ed. Stuttgart, FK Schattauer Verlag, 1982.)

and symptoms of appendicitis. Changes of this type tend to subside as the Koplik spots disappear. Otitis media, bronchopneumonia, and gastrointestinal symptoms such as diarrhea and vomiting are more common in infants and small children (especially if they are malnourished) than in older children.

ATYPICAL MEASLES.

Atypical measles occurs in recipients of killed measles virus vaccine, which was used from 1963 to 1967, who later come in contact with wild-type measles virus. Typical measles prodromal symptoms, except for fever, occur infrequently. Atypical measles is characterized by severe headache, severe abdominal pain, often with vomiting, myalgias, respiratory symptoms, pneumonia with pleural effusion, and an exanthem that is very different from the typical measles rash. The atypical measles rash first appears on the palms, wrists, soles, and ankles, and progresses in a centripetal direction. The lesions are initially maculopapular but become vesicular and later may become purpuric or hemorrhagic. Koplik spots rarely appear in patients with atypical measles.

Diagnosis.

The diagnosis is usually apparent from the characteristic clinical picture; laboratory confirmation is rarely needed. However, because indigenous measles rarely occurs in the United States, it is important to confirm suspected infection serologically. Testing for measles IgM antibodies is recommended, which is provided free of charge by the Centers for Disease Control and Prevention or by the state health department. Measles IgM is detectable for 1 mo after illness, but sensitivity of IgM assays may be limited in the first 72?hr of the rash illness. Isolation of measles virus from clinical samples is also useful in identifying the genotype of the strain to track transmission patterns. All suspected measles cases should be reported immediately to local or state health departments. During the prodromal stage multinucleated giant cells can be demonstrated in smears of the nasal mucosa. Antibodies become detectable when the rash appears; testing of acute and convalescent sera demonstrates the diagnostic seroconversion or fourfold increase in titer. Measles virus can be isolated by tissue culture in human embryonic or rhesus monkey kidney cells. Cytopathic changes, visible in 5–10 days, consist of multinucleated giant cells with intranuclear inclusions.

The white blood cell count tends to be low with a relative lymphocytosis. Cerebrospinal fluid in patients with measles encephalitis usually shows an increase in protein and a small increase in lymphocytes. The glucose level is normal.

The diagnosis of measles is frequently delayed in adults because practitioners providing health care for adults are not used to encountering the disease and rarely include it in the differential diagnosis. The clinical picture is similar to that seen in children. Liver involvement, with abdominal pain, mild to moderate elevation of aspartate aminotransferase (AST) levels, and occasionally jaundice, is common in adults.

DIFFERENTIAL DIAGNOSIS.

The rash of rubeola must be differentiated from that of rubella; roseola infantum (human herpesvirus 6); infections resulting from echovirus, coxsackievirus, and adenovirus; infectious mononucleosis; toxoplasmosis; meningococcemia; scarlet fever; rickettsial diseases; Kawasaki disease; serum sickness; and drug rashes.

Koplik spots are pathognomonic for measles. The rashes of rubella and of enteroviral and adenoviral infections tend to be less striking than that of measles, as do the degree of fever and severity of illness. The rash of roseola infantum appears as the fever disappears, whereas in measles it appears concomitantly. Although cough is present in many rickettsial infections, the rash usually spares the face, which is characteristically involved in measles. The absence of administration of a drug in the history usually serves to exclude serum sickness or drug rashes. Meningococcemia may be accompanied by a rash that is somewhat similar to that of measles, but cough and conjunctivitis are usually absent. In acute meningococcemia the rash is

characteristically petechial and purpuric. The diffuse, finely papular rash of scarlet fever has a “goose flesh” texture on an erythematous base and is relatively easy to differentiate from the maculopapular rash of measles.

Treatment.

There is no specific antiviral therapy; treatment is entirely supportive. Antipyretics (acetaminophen or ibuprofen) for fever, bed rest, and maintenance of an adequate fluid intake are indicated. Humidification may alleviate symptoms of laryngitis or an excessively irritating cough; it is best to keep the room comfortably warm rather than cool. Patients with photophobia should be protected from exposure to strong light. Bacterial complications of otitis media and bronchopneumonia require appropriate antimicrobial therapy.

Complications such as encephalitis, subacute sclerosing panencephalitis, giant cell pneumonia, and disseminated intravascular coagulation must be assessed individually. Good supportive care is essential. Immunoglobulin and corticosteroids are of limited value. Currently available antiviral compounds are not effective.

VITAMIN A.

Hyporetinemia is present in more than 90% of cases of measles in Africa and in approximately 22–72% of children with measles in the United States; there is an apparent inverse correlation between retinol concentration and measles severity. Treatment with oral vitamin A reduces morbidity and mortality in children with severe measles in the developing world. Although data to determine the need for vitamin A supplementation for children with measles in the United States are incomplete, the American Academy of Pediatrics recommends consideration of vitamin A supplementation for children 6 mo to 2 yr of age who are hospitalized for measles and its complications and for children older than 6 mo of age with measles and immunodeficiency; ophthalmologic evidence of vitamin A deficiency (e.g., night blindness, Bitot spots, or evidence of xerophthalmia); impaired intestinal absorption (e.g., biliary obstruction, short-bowel syndrome, cystic fibrosis); moderate to severe malnutrition; or recent immigration from areas where high mortality rates from measles have been observed. The recommended regimen is a single dose of 100,000?IU orally for children 6 mo to 1 yr, and 200,000?IU for children 1 yr of age

or older. Children with ophthalmologic evidence of vitamin A deficiency should be given additional doses the next day and 4 wk later.

Complications.

The chief complications of measles are otitis media, pneumonia, and encephalitis. Noma of the cheeks may occur in rare instances. Gangrene elsewhere appears to be secondary to purpura fulminans or disseminated intravascular coagulation following measles. Interstitial pneumonia may be caused by the measles virus (giant cell pneumonia). Measles pneumonia in HIV-infected patients is often fatal and is not always accompanied by rash. Bacterial superinfection and bronchopneumonia are more frequent, however, usually with pneumococcus, group A *Streptococcus, Staphylococcus aureus*, and *Haemophilus influenzae* type b. Laryngitis, tracheitis, and bronchitis are common and may be due to the virus alone. Measles may exacerbate underlying *Mycobacterium tuberculosis* infection. There may also be a temporary loss of hypersensitivity reaction to tuberculin skin testing. Myocarditis is an infrequent serious complication, although transient electrocardiographic changes may be relatively common.

Neurologic complications are more common in measles than in any of the other exanthematous diseases. The incidence of encephalomyelitis is estimated to be 1–2/1,000 cases of measles. There is no correlation between the severity of the rash illness and that of the neurologic involvement, or between the severity of the initial encephalitic process and the prognosis. Infrequently, encephalitic involvement is manifest in the pre-eruptive period, but more often its onset occurs 2–5 days after the appearance of the rash. The cause of measles encephalitis remains controversial. It has been suggested that direct viral invasion may be operative for encephalitis early in the course of the disease, although measles virus has rarely been isolated from brain tissue. Encephalitis that occurs later is predominantly demyelinating and may reflect an immunologic reaction. In this demyelinating type the symptoms and course do not differ from those of other parainfectious encephalitides. Fatal encephalitis has occurred in children receiving immunosuppressive treatment. Other central nervous system complications, including Guillain-Barré syndrome, hemiplegia, cerebral thrombophlebitis, and retrobulbar neuritis, occur rarely.

Prognosis.

Case fatality rates in the United States have decreased in recent years to low levels for all age groups, largely because of improved socioeconomic conditions but also because of effective antibacterial therapy for the treatment of secondary bacterial infections. Despite the decline in measles cases and fatalities in the United States, the case fatality rate is still 1–3/1,000 cases. Deaths are primarily due to pneumonia or secondary bacterial infections. In developing countries measles frequently occurs in infants; possibly because of concomitant malnutrition, the disease is very severe in these locations and has a high mortality.

When measles is introduced into a highly susceptible population, the results may be disastrous. Such an occurrence in the Faroe Islands in 1846 resulted in the deaths of about one fourth, nearly 2,000, of the total population. At Ungava Bay, Canada, where 99% of 900 persons contracted measles, the mortality rate was 7%.

Prevention.

Isolation precautions, especially in hospitals and other institutions, should be maintained from the 7th day after exposure until 5 days after the rash has appeared.

VACCINE.

The initial measles immunization, usually as measles-mumps-rubella (MMR) vaccine, is recommended at 12–15 mo of age but may be given for measles postexposure and outbreak prophylaxis as early as 6 mo of age. A second immunization, also as MMR, is recommended routinely at 4–6 yr of age but may be administered at any time during childhood provided at least 4 wk have elapsed since the first dose. Children who have not previously received the second dose should be immunized by 11–12 yr of age. Adolescents entering college or the workforce should have received a second measles immunization.

The response to live measles vaccine may be abrogated if immunoglobulin has been recently administered (see Chapter 282). Anergy to tuberculin skin testing may develop and can persist for longer than 1 mo after measles vaccination. Children with active tuberculous infection should be receiving antituberculosis treatment when measles vaccine is administered. A tuberculin test prior to or concurrent with active immunization against measles is desirable if tuberculosis is under consideration.

Measles vaccine is not recommended for pregnant women, children with primary immunodeficiency, untreated tuberculosis, cancer, or organ transplantation, those receiving long-term immunosuppressive therapy, or severely immunocompromised HIV-infected children. HIV-infected children without severe immunosuppression and without evidence of measles immunity may receive measles vaccine.

POSTEXPOSURE PROPHYLAXIS.

Passive immunization with immune globulin is effective for prevention and attenuation of measles within 6 days of exposure. Susceptible household and hospital contacts who are younger than 12 mo of age or who are pregnant should receive immune globulin (0.25?mL/kg; maximum: 15?mL) intramuscularly as soon as possible after exposure, but within 5 days. Immunocompromised persons should receive immune globulin (0.5?mL/kg; maximum: 15?mL) intramuscularly regardless of immunization status. Infants 6 mo of age or younger born to nonimmune mothers should receive immune globulin; infants 6 mo of age or younger born to immune mothers are considered protected by maternal antibody. Susceptible children 6–12 mo of age should also be vaccinated; this vaccination does not count as one of the two required measles vaccinations. Susceptible children 12 mo of

age or older should receive vaccine alone within 72?hr. Pregnant women and immunocompromised persons should receive immune globulin but not vaccine.

225.1 Subacute Sclerosing Panencephalitis

Etiology.

Subacute sclerosing panencephalitis (Dawson encephalitis) is a chronic encephalitis caused by persistent measles virus infection of the central nervous system. Dawson was the first to describe it clearly and to postulate a viral cause. Subsequently, measles virus was isolated from the brains of patients with subacute sclerosing panencephalitis (SSPE).

Epidemiology.

SSPE is a rare disease that occurs worldwide. The disease has been diagnosed in patients 6 mo to older than 30 yr of age, but it affects primarily children and young adolescents. In more than 85% of cases, onset occurs from 5 to 15 yr of age. Infection with measles at younger than 18 mo of age seems to increase the risk of SSPE substantially. The risk among boys is more than twice that among girls, and it is higher among rural children than city children, children with more than two siblings, and children of lower socioeconomic status. SSPE was once especially common in the southeastern United States, the Ohio River valley, and some New England states. Recently, cases have been more common in the western United States and in New York City, especially among Hispanic immigrant children. Exposure to birds and other animals has been reported with abnormal frequency in the histories of patients with SSPE; the reason is not clear.

The annual incidence of SSPE in the United States fell markedly from 0.61 cases per 1 million persons younger than 20 yr of age in 1960 to 0.06 cases per 1 million in 1980. Since 1982, fewer than five new cases in the entire country have been registered with the U.S. National SSPE Registry each year. The decrease roughly parallels the progressive decline in the annual number of measles cases diagnosed since the introduction of live attenuated measles vaccine in the United States in 1963. The risk of SSPE has been estimated at 8.5 SSPE cases per 1 million cases of measles for a 6-yr period, during which the estimated risk after measles vaccination was only 0.7 cases per 1 million doses of vaccine. The overwhelming advantage of measles vaccination in preventing SSPE is clear.

In a recent case control study, the lack of vaccination was a highly significant risk factor for SSPE, and in a survey in England and Wales the relative risk of SSPE after measles infection was 29 times that of the risk of SSPE after measles vaccination. In cases occurring in vaccinated children, it has not been determined whether SSPE resulted from persistent infection with the attenuated measles virus of the vaccine, from undiagnosed wild-type measles infection preceding vaccination, or from vaccine failure and subsequent undiagnosed measles. SSPE continues to occur in areas of the world where measles remains unchecked and may be anticipated to increase wherever compliance with vaccination protocols diminishes.

Children with SSPE generally have a history of typical measles, which may have been either mild or severe, with full recovery several years before the onset of neurologic disease. Some patients with SSPE have had measles pneumonia, but none have had a history of typical measles encephalitis. The mean interval between measles and onset of SSPE was formerly about 7 yr, but recently it has increased to 12 yr. In vaccinated patients without a history of measles, the mean interval between vaccination and onset of SSPE was 5 yr before 1980 and 7.7 yr between 1980 and 1986.

Pathogenesis.

The histopathology of SSPE consists of inflammation, necrosis, and repair. Brain biopsy performed in the early stages of SSPE shows mild inflammation of the meninges and a panencephalitis involving cortical and subcortical gray matter as well as white matter, with cuffs of plasma cells and lymphocytes around blood vessels (Fig. 225–3) and increased numbers of glia throughout. Neuronal loss may not be marked until later in the course of the illness, when loss of myelin secondary to neuronal degeneration may be apparent. Intranuclear inclusion bodies surrounded by clear halos (**Cowdry type A**) may be seen within the nuclei of neurons, astrocytes, and oligodendrocytes. On electron microscopy, the inclusions are seen to contain tubular structures typical of the nucleocapsids of paramyxoviruses. Measles viral antigens can be demonstrated by labeled antibody techniques within the inclusions as well as in cells without inclusions. Lesions may be unevenly distributed throughout the brain, and biopsy is not always diagnostic.

The same findings of inclusion-body panencephalitis are generally present at autopsy; however, late in the disease it may be difficult to find typical areas of inflammation, and the main histopathologic changes are necrosis and gliosis. The disease is believed to begin in the cortical gray matter, progressing then to the subcortical white and gray matter (myoclonus probably results from extrapyramidal involvement) and finally to the lower structures. Although persistent infection of lymphoid tissues with measles virus has been reported, these show no pathologic changes.

It has been proposed that viral mutation may render the measles virus more likely to establish persistent central nervous system (CNS) infection, and multiple mutations have been found in isolates from patients with SSPE. However, no consistent genomic abnormalities have been identified in those isolates, and clusters of SSPE cases suggestive of strains of special virulence have been described only rarely. It has also been theorized that patients with SSPE have subtle predisposing immune deficiency; the markedly increased risk of SSPE after measles in infancy suggests that either immunologic immaturity or persistence of maternal antibodies to measles virus is involved in the later occurrence of the disease.

Complete measles virus particles are not found in the brains of patients with SSPE, and the matrix (M) protein required for the final assembly and budding of virus from the host cells is missing not only from the brain tissue of patients but also from cells cultured from their brains; however, the full complement of genetic material needed to code for all proteins, including the M protein, is present and functional. Several studies have suggested that M proteins are encoded but that because of a variety of mutations they cannot bind to nucleocapsid, resulting in

Figure 225.1-3 A cuff of inflammatory cells surrounds a blood vessel in the cerebral cortex of a child with subacute sclerosing panencephalitis. (Courtesy of Janice Stevens, MD, National Institute of

Mental Health, and Peggy Swoveland, MD, University of Maryland School of Medicine.)

accumulation of incomplete measles virus that cannot be cleared either by antibodies or by cell-mediated immunity.

Clinical Manifestations.

The clinical picture of SSPE tends to be quite stereotypical; almost 70% of cases have an acute, subacute, or chronic progressive course; fewer than 10% have remissions. The onset is usually insidious and is marked by subtle changes in behavior and deterioration of schoolwork; this is followed by more overtly bizarre behavior and finally by frank dementia.

There is no fever, photophobia, or other findings of acute encephalitis except for occasional complaints of headache. Diffuse neurologic disease becomes progressively more severe. The appearance of massive, repetitive myoclonic jerks, generally symmetric, involving especially the axial musculature and occurring at 5–10-sec intervals, marks the onset of the second clinical stage of SSPE. The myoclonic jerks appear to be abnormal movements rather than epileptic seizures, but true convulsions can also occur at any stage of the illness. In addition to myoclonic jerks, which tend to disappear as the disease progresses, a variety of other abnormal movements and dystonias have been observed. Cerebellar ataxia may occur. Retinopathy and optic atrophy may appear, sometimes even before the behavioral changes. Dementia progresses to stupor and coma, sometimes with autonomic insufficiency. Patients may be rigid or spastic with decorticate postures, or they may be flaccid.

The speed of progression is highly variable, but in at least 60% of patients the course is inexorable and relatively rapid. The total duration of illness may be as short as a few months, but most patients survive for 1–3 yr after diagnosis, with a mean of about 18 mo. Occasional patients show some spontaneous improvement and live for more than 10 yr. In recent years, the few patients diagnosed with SSPE in the United States have tended to have a relatively long survival, perhaps because of improvements in chronic care.

Diagnosis.

Blood tests are normal except for elevated titers of antibodies to measles virus; IgG and IgM antibodies are directed against all the component proteins of measles virus except the M protein. Cell content of the cerebrospinal fluid (CSF) is generally normal, although stained sediments may show plasma cells. Total protein content of the CSF is normal or only slightly elevated; however, the gamma globulin fraction is greatly elevated (usually comprising at least 20% of total protein), resulting in a paretic type of colloidal gold curve. When the CSF is examined by electrophoresis or isoelectric focusing, oligoclonal bands of Ig are often observed. IgG and IgM antibodies to measles virus, not normally found in unconcentrated CSF, make up most of the Ig, and these can often be detected in dilutions of 1:8 or more. The complement fixation test has been especially useful for demonstrating antibodies in CSF, but hemagglutination inhibition, immunofluorescence, and other serologic tests, including enzyme-labeled immunosorbent assays (ELISA), are also satisfactory. The usual ratio of antibody in serum to CSF is reduced (<1:200) for measles antibodies, whereas the serum-to-CSF ratio is normal for other viral antibodies and for albumin, indicating that the increased amounts of measles antibodies in the CSF of patients with SSPE result from synthesis within the nervous system and that the blood-brain barrier is normal.

Early in the course of disease, the electroencephalogram (EEG) may be normal or show only moderate nonspecific slowing. In the myoclonic stage, most patients with SSPE have “suppression-burst episodes” in which high-amplitude slow and sharp waves recur at intervals of 3–5?sec on a slow background; however, this pattern is not unique to SSPE. Later in the illness, the EEG becomes increasingly disorganized and shows high-amplitude, random dysrhythmic slowing; in terminal disease, the amplitude may fall.

CT or MRI scans of patients with SSPE may show variable cortical atrophy and ventricular enlargement, and there may be focal or multifocal low-density lesions in the white matter. However, these studies may be normal, especially early in the disease.

Brain biopsy is no longer needed to diagnose SSPE. When performed, it often shows the typical histopathologic findings described earlier. Examination of frozen sections by immunofluorescence techniques may demonstrate the presence of measles viral antigens. Persistence of measles virus infection in cultures may be demonstrated by labeled antibody techniques before the complete virus appears. Many specimens fail to yield complete virus. Modifications of the polymerase chain reaction can detect various regions of the measles virus RNA in frozen and even paraffin-embedded brain tissue specimens of patients with SSPE. Nucleic acid hybridization techniques have also been used to demonstrate the measles viral genome.

DIFFERENTIAL DIAGNOSIS.

It is most important to rule out potentially treatable illnesses such as bacterial infections and tumors. The diverse cerebral storage diseases and nonstorage poliodystrophies, leukodystrophies, and demyelinating diseases of childhood can also produce progressive dementia with seizures and paralysis resembling SSPE. Early in the course of illness, SSPE must be distinguished from atypical acute viral encephalitides. Other slow viral infections, such as Creutzfeldt-Jakob disease (CJD) and progressive rubella panencephalitis, must be considered in appropriate age groups. The presence of a typical EEG pattern suggests SSPE, as do unusually high levels of measles antibodies in serum. The diagnosis is practically confirmed if measles antibodies are detected in CSF.

The persistent measles infection seen in SSPE does not result in complete virus particles. Patients with SSPE, therefore, pose no hazard of infection to others, and no special precautions need ordinarily be taken. Blood precautions might be justified under special circumstances.

Treatment.

Administration of inosiplex (100?mg/kg/24?hr) may prolong survival and may produce some clinical improvement in the degree of disability. Other treatments have been ineffective. The use of anticonvulsants, maintenance of nutritional status, prompt treatment of secondary bacterial infections, physical therapy, and other supportive care may also prolong survival and improve the quality of life for the patient and family. Information on current therapeutic trials can be obtained from the U.S. National SSPE Registry (Dr. Paul R. Dyken, Institute for Research in Childhood Neurodegenerative Diseases, Mobile, Alabama; Telephone 334-478-6424).

Complications.

Patients with SSPE have the usual secondary complications associated with incapacitating neurologic diseases, such as recurrent pneumonias and decubitus ulcers.

Prognosis.

Few patients live for longer than 3 yr after the diagnosis of SSPE, and those who do survive longer are usually disabled.

Prevention.

Measles vaccination is the most important measure to prevent SSPE.

Chapter 226 - Rubella

Yvonne Maldonado

Rubella (**German** or **three-day measles**) is an important childhood disease that was historically widespread but is now very infrequent. It is an acute viral infection ordinarily characterized by mild constitutional symptoms, a rash similar to that of mild rubeola or scarlet fever, and enlargement and tenderness of the postoccipital, retroauricular, and posterior cervical lymph nodes. Rubella in early pregnancy may cause the congenital rubella syndrome, a serious multisystem disease with a wide spectrum of clinical expression and sequelae.

Etiology.

Rubella virus, the cause of rubella, is an RNA virus of the genus *Rubivirus* in the family Togaviridae.

Epidemiology.

Humans are the only natural host of rubella virus, which is spread either by oral droplet or transplacentally to the fetus, causing congenital infection. It is distributed worldwide and affects both sexes equally. Before introduction of the rubella vaccine in 1969, pandemics of rubella occurred every 6–9 yr, with most cases occurring in the spring. In 1964–1965, an epidemic in the United States caused more than 12 million cases of rubella and an additional 20,000 infants with congenital rubella syndrome. The peak incidence of rubella was among children 5–14 yr of age but most cases now occur among susceptible teenagers and young adults. Outbreaks have been reported among college students and in unvaccinated populations, such as Amish communities, and among unvaccinated foreign-born adults. In closed populations, such as institutions and military barracks, almost 100% of susceptible individuals may become infected. In family settings, 50–60% of susceptible family members acquire the disease.

Indigenous rubella and congenital rubella syndrome were targeted for elimination in the United States by the year 2000. From a peak of 57,686 cases in 1969 through 1989, the numbers of annual reported cases have decreased, with a slight resurgence during 1990–1991, by 99.7% to 128–192 cases of rubella and 4–11 cases of congenital rubella syndrome annually from 1992 to 1997. In 2001, only 20 cases of rubella were reported in the United States. Despite these advances, outbreaks of rubella and congenital rubella still occur, primarily among unvaccinated foreign-born adults.

During clinical illness the virus is shed in nasopharyngeal secretions, blood, feces, and urine. Virus has been recovered from the nasopharynx 7 days before exanthem and 7–8 days after its disappearance. Patients with subclinical disease are also infectious.

Pathogenesis.

The pathogenesis of rubella is not well understood. Virus can be found from both infected and uninfected areas of skin, suggesting that immune processes may be important.

The risk for congenital defects and disease is greatest with primary maternal infection during the first trimester. Congenital defects occur in about 90% of infants whose mothers acquire maternal infection before the 11th week of pregnancy, diminishing to about 10–20% by the end of the first trimester, with an overall risk for the trimester being about 70%. Maternal infection after the 16th week of pregnancy poses a low risk for congenital defects, although infection of the fetus may occur.

Clinical Manifestations.

The incubation period is 14–21 days. The prodromal phase of mild catarrhal symptoms is shorter than that of measles and may be so mild that it goes unnoticed. Approximately two thirds of infections are subclinical.

The most characteristic sign is retroauricular, posterior cervical, and postoccipital lymphadenopathy. No other disease causes the tender enlargement of these nodes to the extent that rubella does. An enanthem appears in 20% of patients just before the onset of the skin rash. It consists of discrete rose-colored spots on the soft palate (**Forchheimer spots**) that may coalesce into a red blush and extend over the fauces.

Lymphadenopathy is evident at least 24?hr before the rash appears and may remain for 1 wk or more. The exanthem is more variable than that of rubeola. It begins on the face (Fig. 226–1) and spreads quickly. Its evolution is so rapid that the rash may be fading on the face by the time it appears on the trunk. Discrete maculopapules are present in large numbers; there are also large areas of flushing that spread rapidly over the entire body, usually within 24?hr. The rash may be confluent, particularly on the face. During the second day the rash may assume a pinpoint appearance, especially over the trunk, resembling that of scarlet fever. Mild itching may occur. The eruption usually clears by the third day. Desquamation is minimal. Rubella without a rash has been described.

The pharyngeal mucosa and the conjunctivae are slightly inflamed. In contrast to rubeola, there is no photophobia. Fever is low grade or absent during the rash and persists for 1, 2, or occasionally 3 days. Anorexia, headache, and malaise are not common.

Especially in older girls and women, polyarthritis may occur with arthralgia, swelling, tenderness, and effusion but usually

Figure 226-1 Rash of rubella (German measles). (From Korting GW: *Hautkrankheiten bei Kindern und Jugendlichen*, 3rd ed. Stuttgart, Germany, FK Schattauer Verlag, 1982.)

without any residuum. Any joint may be involved, but the small joints of the hands are affected most frequently. The duration is usually several days to 2 wk; rarely it persists for months. Paresthesia also has been reported.

CONGENITAL RUBELLA SYNDROME.

See Complications.

Diagnosis.

The diagnosis of rubella may be apparent from the clinical symptoms and physical examination, but it is usually confirmed by serology or virus culture. The spleen is often slightly enlarged. The white blood cell count is normal or slightly reduced; thrombocytopenia is rare, with or without purpura. Hemagglutination-inhibition (HI) antibody has been the reference method of determining immunity to rubella, but newer methods that are easier to perform are now used more commonly. Latex agglutination, enzyme immunoassay, passive hemagglutination, and fluorescent immunoassay appear to be equal or superior to the HI test in sensitivity. Immunoglobulin (Ig) M antibodies are detectable in the first few days of illness and are considered diagnostic. Detection of IgM antibodies, which do not cross the placenta, in the newborn is especially useful for the diagnosis of congenital rubella syndrome. Seroconversion, or a fourfold increase in IgG titer, is diagnostic.

Rubella virus can be cultured from the nasopharynx and blood. It is detected by the ability of rubella-infected African green monkey kidney (AGMK) cells to resist challenge with enterovirus.

DIFFERENTIAL DIAGNOSIS.

Because similar symptoms and rashes can occur with many other viral infections, rubella is a difficult disease to diagnose clinically except when the patient is seen during an epidemic. A history of having had rubella or rubella vaccine is unreliable; immunity should be determined by antibody testing. Particularly in its more severe forms, rubella may be confused with the mild types of scarlet fever and rubeola. Roseola infantum (exanthem subitum) is distinguished by a higher fever and the appearance of the rash at the end of the febrile episode rather than at the height of the signs and symptoms. Infectious mononucleosis may have a rash but is associated with generalized lymphadenopathy and characteristic atypical lymphocytosis. Enteroviral infections accompanied by a rash can be differentiated in some instances by accompanying respiratory or gastrointestinal manifestations and the absence of retroauricular lymphadenopathy. Drug rashes may be extremely difficult to differentiate from the rash of rubella, but the characteristic enlargement of the lymph nodes strongly supports a diagnosis of rubella.

Treatment.

There is no specific antiviral therapy; treatment is entirely supportive. Antipyretics (acetaminophen or ibuprofen) are indicated for fever.

Complications.

Complications are relatively uncommon in childhood. Encephalitis similar to that seen with measles occurs in about 1 in 6,000 cases. The severity is highly variable, and there is an overall mortality rate of 20%. Symptoms in survivors usually resolve within 1–3 wk without neurologic sequelae. Thrombocytopenic purpura occurs at an overall rate of 1 in 3,000 cases.

The most important consequence of rubella in a pregnant woman is congenital rubella syndrome. Progressive rubella panencephalitis is a persistent, slowly progressive rubella infection of the central nervous system (see Chapter 226.1).

CONGENITAL RUBELLA SYNDROME.

Congenital rubella affects virtually all organ systems. The most common manifestation is intrauterine growth retardation. Other common findings include cataracts, bilateral or unilateral, which are frequently associated with microphthalmia; myocarditis and structural cardiac defects (e.g., patent ductus arteriosus or pulmonary artery stenosis); “blueberry muffin” skin lesions, similar to those seen in congenital cytomegalovirus infection; hearing loss from sensorineural deafness; and meningoencephalitis. Persistent infection leads to pneumonia, hepatitis, bone lucencies, thrombocytopenic purpura, and anemia. Later sequelae include motor and mental retardation.

The diagnosis is confirmed by finding rubella-specific IgM antibody in the neonatal serum, or by culturing rubella virus from the infant (nasopharynx, urine, or tissues). Virus can be shed in the urine for 1 yr or longer. Prenatal diagnosis of fetal rubella infection can be made either by isolating the virus from amniotic fluid or by identification of rubella-specific IgM in cord blood.

Infants with the complete spectrum of the congenital rubella syndrome have a grim prognosis, especially when the neurologic symptoms continue to progress throughout infancy. The prognosis is better for infants with fewer stigmata of the syndrome, presumably those who were initially infected later in gestation. Only about 30% of infants with encephalitis appear to escape residual neuromotor deficitis, including an autistic syndrome.

Prognosis.

The prognosis of rubella in childhood is excellent. Infection usually confers

permanent immunity, although reinfection may occur.

REINFECTION.

The incidence of reinfection on exposure to wild virus is 3–10% among those with a history of previous rubella and 14–18% among those immunized with the RA 27/3 vaccine. Reinfection may lead only to an IgG booster response, to both an IgM and IgG response, or to clinical rubella. Maternal reinfection during pregnancy has resulted in congenital rubella syndrome. The significance of rubella reinfection is controversial.

Prevention.

Rubella vaccine is derived from the RA 27/3 strain of rubella virus, which is attenuated by serial passage tissue culture in WI-38 and MRC-5 human diploid cells. The vaccine induces antibody in more than 99% of seronegative recipients and has protective efficacy in more than 90%. Vaccine virus may be shed from the nasopharynx in low titers for as long as 18–25 days after vaccination, although there is no evidence of communicability.

The initial rubella immunization, usually as measles-mumps-rubella (MMR), is recommended at 12–15 mo of age. A second immunization, also as MMR, is recommended routinely at 4–6 yr of age but may be administered at any time during childhood provided at least 4 wk have elapsed since the first dose. Children who have not previously received the second dose should be immunized by 11–12 yr of age. It is especially important for girls to have immunity to rubella before they reach childbearing age.

Pregnant women should not be given live rubella virus vaccine and should avoid becoming pregnant for 3 mo after they have been vaccinated. Routine serologic testing of postpubertal women before rubella immunization is not necessary. Inadvertent immunization is not ordinarily a reason to interrupt the pregnancy. No cases of congenital rubella syndrome have been reported in more than 200 women immunized during pregnancy with RA 27/qa3 vaccine who have been studied. Other contraindications include allergy to a vaccine component (anaphylaxis to neomycin), moderate or severe acute illness with or without fever, immunodeficiency (primary immunodeficiency, cancer and cancer therapy, long-term high-dose corticosteroids, severely immunocompromised, including those with HIV infection), and recent immunoglobulin administration (see Chapter 282).

Symptoms that may follow rubella immunization include fever (5–15%), rash (5%), lymphadenopathy, and arthralgias and arthritis. Joint involvement, usually seen in the small peripheral joints 10–21 days after vaccination, is uncommon in children but occurs frequently in postpubertal females with both arthralgias (25%) and transient arthritis (10%) being reported. It may last for weeks. Transient peripheral paresthesia and pain in the arms and legs are reported rarely.

All health care workers should be immune to rubella as well as to measles and varicella. Persons born before 1957 can be

considered immune to rubella, except women of childbearing age who could become pregnant. Adolescent girls and premenopausal women should either be vaccinated or have documented laboratory evidence of immunity. Maternal antibody is protective for the infant for the first 6 mo of life.

POSTEXPOSURE PROPHYLAXIS.

Nonpregnant susceptible contacts of persons with rubella should be vaccinated. This does not prevent infection but ensures protection for future rubella exposures.

All pregnant women, regardless of immunization history, should make every effort to avoid exposure to rubella. If a pregnant woman whose immune status is unknown is exposed to rubella, an antibody test should be performed immediately. Immune women should be reassured. Susceptible pregnant women exposed to rubella should not receive vaccine because of the potential risk of transmission of vaccine virus to the fetus. Susceptible women should undergo repeat serologic testing 3–4 wk after exposure, and, if they are still seronegative, again 6 wk after exposure. Seroconversion on either specimen indicates infection, and the mother should be counseled about the risk of transmission to the fetus and the resulting anomalies. Routine immune globulin administration for postexposure prophylaxis in pregnancy is not recommended but should be considered if termination of the pregnancy is not an option. For the susceptible pregnant woman exposed to measles for whom termination of pregnancy is a viable option and for whom timing permits documentation of seroconversion within the period of time when abortion is possible, immune globulin is not recommended because it may provide an unjustified sense of security and precludes a positive serologic diagnosis as the basis for termination of pregnancy. However, for the susceptible pregnant woman exposed to rubella for whom abortion is not an option, immunoglobulin should be administered in a dose of 0.55?mL/kg, which reduces the attack rate but does not eliminate the risk of fetal infection. Fetal infection may occur even in the absence of clinical signs in the mother. The use of intravenous immunoglobulin (IVIG) may be an alternative but has not been studied.

226.2 Progressive Rubella Panencephalitis

Epidemiology.

Progressive rubella panencephalitis is an exceedingly rare form of chronic encephalitis associated with persistent rubella virus infection of the brain. Since the disease was first recognized in 1974, 20 cases have been reported, all involving males 8–21 yr of age at onset. Most had typical stigmata of the congenital rubella syndrome including cataracts, deafness, and mental retardation, but two had apparently had childhood rubella from which they made a full recovery. No new cases have been described in the United States in recent years, presumably because of effective childhood rubella immunization programs.

Pathogenesis.

Rubella virus has been isolated from brain cell cultures and from blood lymphocytes. The histopathologic changes seen in the brain are similar to those seen in SSPE, with cuffs of lymphocytes and plasma cells around blood vessels, glial nodules in the cortex, some loss of neurons, an increase in astrocytes throughout the gray matter, and an even greater increase in the white matter. However, in progressive rubella panencephalitis, there are no inclusion bodies, and deposits of material that stains with the periodic acid-Schiff reaction are found around vessels in subcortical white matter.

Clinical Manifestations.

At onset, progressive rubella panencephalitis resembles subacute sclerosing panencephalitis (SSPE; see Chapter 225.1), with insidious changes in behavior and deteriorating school performance. Subsequently, frank dementia and other signs of multifocal brain disease occur, including seizures, cerebellar ataxia, and spastic weakness. Myoclonus and other abnormal movements may occur but are not as common as those seen in SSPE. Retinopathy and optic atrophy may occur.

Diagnosis.

Early in the course of illness, progressive rubella panencephalitis must be distinguished from atypical acute viral encephalitides. Other slow viral infections, such as Creutzfeldt-Jakob disease (CJD) and SSPE, must be considered in appropriate age groups. Stigmata of congenital rubella syndrome or rubella infection suggest the diagnosis of progressive rubella panencephalitis.

Remarkable laboratory abnormalities include elevated antibody titers to rubella virus, a normal or slightly elevated CSF cell count, and a slightly elevated CSF protein concentration with a marked increase in globulin, which may constitute more than 50% of the total protein. Oligoclonal electrophoretic bands of globulin consist of antibodies to rubella virus antigens. Antibodies to rubella virus are readily detectable in CSF, often at dilutions of 1:8 or higher. The hemagglutination-inhibition, complement fixation, and enzyme immunoassay techniques should be satisfactory for testing the cerebrospinal fluid. Most of the rubella antibodies in the CSF are IgG, although some IgM antibodies have also been detected early in the course of progressive rubella panencephalitis. There is a high CSF:serum ratio of rubella antibody titers compared with ratio of titers to measles and other viruses. Isolation of rubella virus from blood lymphocytes may be attempted, but brain biopsy should not be needed to establish the diagnosis.

The EEG shows a generalized slowing with occasional high-voltage activity, but the suppression-burst pattern of SSPE has not been seen in progressive rubella panencephalitis. Encephalograms (computed tomography was not available when published cases were studied) show enlargement of all ventricles, especially the fourth, with prominent atrophy of the cerebellum.

Prognosis.

The course of progressive rubella panencephalitis is similar to that seen in SSPE, progressing to coma, spasticity, brainstem involvement, and death in 2–5 yr.

Patients with progressive rubella panencephalitis pose no substantial risk of infection to others. Rubella viruria has not been detected.

Prevention.

Rubella vaccination is the most important measure to prevent rubella panencephalitis.

Chapter 227 - Mumps

Yvonne Maldonado

Mumps is an important childhood disease that was historically widespread but now occurs very infrequently. It is an acute viral infection characterized by painful enlargement of the salivary glands, chiefly the parotids, as the usual presenting sign.

Etiology.

Mumps virus, the cause of mumps, is an RNA virus of the genus *Paramyxovirus* in the family Paramyxoviridae, which also includes the parainfluenza viruses. Only one serotype is known.

Epidemiology.

Mumps is endemic in most unvaccinated populations; the virus is spread from human reservoir by direct contact, airborne droplets, fomites contaminated by saliva, and possibly by urine. It is distributed worldwide and affects both sexes equally. Before introduction of the vaccine in 1967, the peak incidence of the disease occurred in children 5–9 yr of age; 85% of infections occurred in children younger than 15 yr of age. Now most cases occur in young adults, producing outbreaks in colleges or in the workplace. Outbreaks appear to be primarily related to a lack of immunization, especially in an underimmunized cohort of children born from 1967–1977, rather than to waning to immunity. Epidemics occur at all seasons but are slightly more frequent in late winter and spring.

There has been a dramatic decrease in the incidence of mumps since the introduction of the mumps vaccine in 1968. Except for a small increase in 1987, the incidence of mumps has steadily decreased in the United States. In 2001 there were 226 reported cases of mumps, a greater than 99% reduction from the 152,209 cases reported in 1968.

Virus has been isolated from saliva as long as 6 days before and up to 9 days after appearance of salivary gland swelling. Transmission does not seem to occur more than 24?hr before the appearance of the swelling or later than 3 days after it has

subsided. Virus has been isolated from urine from the 1st–14th day after the onset of salivary gland swelling.

Pathogenesis.

After entry into the last and initial multiplication in the cells of the respiratory tract, the virus is bloodborne to many tissues, among which the salivary and other glands are the most susceptible.

Clinical Manifestations.

The incubation period ranges from 14–24 days, with a peak at 17–18 days. Approximately 30–40% of infections are subclinical. In children, prodromal manifestations are rare but may be manifest by fever, muscular pain (especially in the neck), headache, and malaise.

SALIVARY GLANDS.

The onset is usually characterized by pain and swelling in one or both parotid glands. The parotid swells characteristically; it first fills the space between the posterior border of the mandible and the mastoid and then extends in a series of crescents downward and forward, being limited above by the zygoma. Edema of the skin and soft tissues usually extends further and obscures the limit of the glandular swelling, so that the swelling is more readily appreciated by sight than by palpation. Swelling may proceed extremely rapidly, reaching a maximum within a few hours, although it usually peaks in 1–3 days. The swollen tissues push the earlobe upward and outward, and the angle of the mandible is no longer visible. Swelling slowly subsides within 3–7 days but occasionally lasts longer. One parotid gland usually swells a day or two before the other, but in approximately one quarter of cases the disease remains unilateral. The swollen area is tender and painful, pain being elicited especially by tasting sour liquids such as lemon juice or vinegar. Redness and swelling about the opening of the Stensen duct are common. Edema of the homolateral pharynx and soft palate accompanies the parotid swelling and displaces the tonsil medially; acute edema of the larynx has also been described. Edema over the manubrium and upper chest wall may occur, probably because of lymphatic obstruction. The parotid swelling is usually accompanied by low-grade fever, but this may be absent.

Although the parotid glands alone are affected in the majority of patients, swelling of the submandibular glands occurs frequently and usually accompanies or closely follows that of the parotid glands. In 10–15% of patients only the submandibular gland(s) may be swollen. Little pain is associated with the submandibular infection, but the swelling subsides more slowly than that of the parotids. Redness and swelling at the orifice of the Wharton duct frequently accompany swelling of the gland. Least commonly, the sublingual glands are infected, usually bilaterally; the swelling is evident in the submental region and in the floor of the mouth.

Diagnosis.

The diagnosis of mumps parotitis is usually apparent from the clinical symptoms and physical examination. When the clinical manifestations are limited to less common lesions, the diagnosis is less clear but may be suspected during an outbreak.

Routine laboratory tests are nonspecific; usually leukopenia is present with relative lymphocytosis. An elevation in serum amylase levels is common; the rise tends to parallel the parotid swelling and then to return to normal within 2 wk.

The microbiologic diagnosis is by serology or virus culture. Enzyme immunoassay for mumps immunoglobulin (Ig) G and IgM antibodies are most commonly used for diagnosis. IgM antibodies are detectable in the first few days of illness and are considered diagnostic. They may remain elevated for weeks to months. IgG antibodies are directed primarily against the fusion (F) protein; cross reactions with parainfluenza viruses may occur. Seroconversion, or a fourfold increase in IgG titer, is diagnostic.

Mumps virus can be cultured from the saliva, cerebrospinal fluid, blood, urine, brain, and other infected tissues. Primary cultures of human or monkey kidney cells are used for viral isolation. Cytopathic effect is occasionally observed, but hemadsorption is the most sensitive indicator of infection.

The mumps skin test is unreliable for diagnosis of mumps and for determination of susceptibility to infection.

DIFFERENTIAL DIAGNOSIS.

Other viral causes of parotitis include HIV infection, influenza, parainfluenza viruses 1 and 3, cytomegalovirus, and coxsackieviruses. Acute suppurative parotitis is a bacterial infection usually caused by *Staphylococcus aureus* in which pus can often be expressed from the duct. A salivary calculus obstructing either a parotid or, more commonly, a submandibular duct causes intermittent swelling. Preauricular or anterior cervical lymphadenitis can be differentiated by the well-defined borders of the lymph node and a location that is completely posterior to the angle of the mandible. Orchitis may also be caused by coxsackieviruses.

Treatment.

There is no specific antiviral therapy; treatment is entirely supportive. Antipyretics (acetaminophen or ibuprofen) are indicated for fever. Bed rest should be guided by the patient's needs, but no evidence indicates that it prevents complications. The diet should be adjusted to the patient's ability to chew. Orchitis should be treated with local support and bed rest. Mumps arthritis may respond to a 2-wk course of a nonsteroidal anti-inflammatory agent or corticosteroids. Salicylates do not appear to be effective.

Complications.

Viremia early in the infection probably accounts for the widespread complications. There is no firm evidence that maternal infection is damaging to the fetus; a possible relationship to endocardial fibroelastosis has not been firmly established. Mumps in

early pregnancy does increase the chance of abortion.

MENINGOENCEPHALOMYELITIS.

This is the most frequent complication in childhood. Its true incidence is hard to estimate

because subclinical infection of the central nervous system, as evidenced by cerebrospinal fluid pleocytosis, has been reported in more than 65% of patients with mumps parotitis. Clinical manifestations occur in more than 10% of patients. The incidence of mumps meningoencephalitis is approximately 250/ 100,000 cases; 10% of these cases occurred in patients older than 20 yr of age. The mortality rate is about 2%. Males are affected three to five times as frequently as females.

The pathogenesis of mumps meningoencephalitis may be either a primary infection of neurons or a postinfectious encephalitis with demyelination. In the first type, parotitis frequently appears at the same time or following the onset of encephalitis. In the latter type, encephalitis follows parotitis by an average of 10 days. Parotitis may in some cases be absent. Aqueductal stenosis and hydrocephalus have been associated with mumps infection. Injecting mumps virus into suckling hamsters has produced similar lesions.

Mumps meningoencephalitis is clinically indistinguishable from meningoencephalitis of other origins (see Chapter 174.2). Moderate stiffness of the neck is seen, but the remaining findings on neurologic examination are usually normal. The cerebrospinal fluid may show a lymphocytic pleocytosis of less than 500 cells/ mm^3 , although occasionally the count may exceed 2,000 cells/mm^3 .

ORCHITIS AND EPIDIDYMITIS.

These complications rarely occur in prepubescent boys but are common (14–35%) in adolescents and adults. The testis is most often infected with or without epididymitis; epididymitis may also occur alone. Bilateral orchitis occurs in approximately 30% of patients. Rarely, there is a hydrocele. The orchitis usually follows parotitis within 8 days. Orchitis may also occur without evidence of salivary gland infection. The onset is usually abrupt, with a rise in temperature, chills, headache, nausea, and lower abdominal pain; when the right testis is implicated, appendicitis may be suggested as a diagnostic possibility. The affected testis becomes tender and swollen, and the adjacent skin is edematous and red. The average duration of illness is 4 days. Approximately 30–40% of affected testes atrophy, leaving a cosmetic imbalance. Infertility is rare even with bilateral orchitis.

OOPHORITIS.

Pelvic pain and tenderness are noted in about 7% of postpubertal female patients. There is no evidence of impairment of fertility.

PANCREATITIS.

Mild or subclinical pancreatic involvement is common, but severe pancreatitis is rare. It may be unassociated with salivary gland manifestations and may be misdiagnosed as gastroenteritis. Epigastric pain and tenderness, which are suggestive, may be accompanied by fever, chills, vomiting, and prostration. An elevated serum amylase value is characteristically present in patients with mumps, with or without clinical manifestations of pancreatitis.

MYOCARDITIS.

Serious cardiac manifestations are extremely rare, but mild infection of the myocardium may be more common than is recognized. Electrocardiographic tracings revealed changes, mostly depression of the ST segment, in 13% of adults in one series. Such involvement may explain the precordial pain, bradycardia, and fatigue sometimes noted among adolescents and adults with mumps.

ARTHRITIS.

Migratory polyarthralgia and even arthritis are occasionally seen in adults with mumps but are rare in children. The knees, ankles, shoulders, and wrists are most commonly affected. The symptoms last from a few days to 3 mo, with a median duration of 2 wk.

THYROIDITIS.

Although it is uncommon in children, a diffuse, tender swelling of the thyroid may occur about 1 wk after the onset of parotitis; antithyroid antibodies subsequently develop.

DEAFNESS.

Unilateral, rarely bilateral, nerve deafness may occur; although the incidence is low (1/15,000 cases), mumps was historically a leading cause of unilateral nerve deafness. The hearing loss may be transient or permanent.

OCULAR COMPLICATIONS.

Dacryoadenitis may occur with painful swelling, usually bilateral, of the lacrimal glands. Optic neuritis (papillitis) may occur; symptoms vary from loss of vision to mild blurring, with recovery in 10–20 days.

Prognosis.

The prognosis of rubella in childhood is excellent. Infection usually confers permanent immunity, although reinfections have been documented.

Prevention.

Mumps vaccine is derived from the **Jeryl Lynn strain** of mumps virus, which is attenuated by serial passage in embryonated hens' eggs and chick embryo cell culture. The vaccine induces antibody in 96% of seronegative recipients and has 97% protective efficacy.

The initial mumps immunization, usually as measles-mumps-rubella (MMR) vaccine, is recommended at 12–15 mo of age. A second immunization, also as MMR, is recommended routinely at 4–6 yr of age but may be administered at any time during childhood provided at least 4 wk have elapsed since the first dose. Children who have not previously received the second dose should be immunized by 11–12 yr of age. Women should avoid becoming pregnant for 30 days after monovalent mumps vaccination (3 mo if vaccination was performed with rubella vaccine). Other contraindications to vaccination include allergy to a vaccine component (anaphylaxis to neomycin), moderate or severe acute illnesses with or without fever, immunodeficiency (primary immunodeficiencies, cancer and cancer therapy, long-term high-dose corticosteroid therapy, severely immunocompromised, including those with HIV infection), and recent immune globulin administration (see Chapter 282). Rarely, parotitis and low-grade fever can develop 10–14 days after vaccination. Vaccinees do not shed virus.

Persons born before 1957 can be considered immune to mumps. Maternal antibody is protective in the infant in the first 6 mo of life.

Chapter 228 - Polioviruses

Eric A. F. Simoes

Etiology.

The polioviruses are non-enveloped, positive-stranded RNA viruses belonging to the Picornaviridae family, in the genus *Enterovirus*, and include three antigenically distinct serotypes (types 1, 2, and 3). Polioviruses spread from the intestinal tract to the central nervous system (CNS), where they cause aseptic meningitis and poliomyelitis, or **polio**. The polioviruses are extremely hardy and can retain activity for several days at room temperature, and can be stored indefinitely frozen at -20°C. They are rapidly inactivated by heat (>56°C), formaldehyde, chlorination, and ultraviolet light. Polioviruses grow well in many cell cultures and rapidly cause cytopathic effects.

Epidemiology.

In 1952 there were 57,879 reported cases of polio in the United States, including 21,269 cases of paralytic polio that resulted in more than 3,000 deaths, with similar epidemics being reported in Europe. These epidemics appeared to affect mostly adolescents and young adults and were growing at a steady pace, which spurred development of the Salk inactivated poliovirus vaccine, and Sabin, Cox, and Koprowski live attenuated vaccines. The universal use of the Salk and Sabin vaccines has resulted in the almost complete global eradication of polio.

The most devastating result of poliovirus infection is paralysis, but more than 90% of infections are asymptomatic or inapparent but do induce protective immunity. Clinically apparent but nonparalytic illness occurs in about 5% of all infections, with paralytic polio occurring in about 1 out of 1,000 infections among infants to about 1 out of 100 infections among adolescents. Prior to the introduction of vaccines in the United States and Europe, improvements in sanitation had limited the fecal-oral spread of polioviruses, resulting in epidemics of infection occurring later in life, when 1 in every 100 infections resulted in paralysis. Thus, in developed countries prior to universal vaccination, epidemics of paralytic poliomyelitis were observed among adolescents. Conversely, in developing countries where sanitation was and continues to be poor, infection early in life results in infantile paralysis. Undoubtedly, good sanitation explains the virtual eradication of polio as a disease from the United States in the early 1960s, when only about two thirds of the population was immunized with the Salk vaccine, and the subsequent absence of circulating wild-type poliovirus in the United States and Europe. In contrast, poor sanitation and crowding have permitted the continued transmission of poliovirus in certain poor countries in Africa and Asia, despite massive global efforts to eradicate polio, in some areas with an average of 12–13 doses of polio vaccine administered to children younger than 5 yr of age.

TRANSMISSION.

Humans are the only known reservoir for the polioviruses. Poliovirus has been isolated from feces more than 2 wk before paralysis to several weeks after the onset of symptoms.

Pathogenesis.

Polioviruses infect cells by adsorbing to specific genetically determined receptors, including poliovirus receptor (PVR). The virus penetrates the cell and is then uncoated and releases RNA. The RNA is translated to produce proteins responsible for replication of the RNA, shut-off of host-cell protein synthesis, and synthesis of structural elements that compose the capsid. Mature virus particles are produced in 6–8?hr and are released into the environment by disruption of the cell.

In the contact host, polioviruses gain entry through the gastrointestinal tract. The pathology of vaccine-associated poliomyelitis (VAPP) mimics natural disease. The primary site of replication may be in M cells lining the mucosa of the small intestine. Regional lymph nodes are infected, and primary viremia occurs after 2–3 days. The virus seeds multiple sites, including the reticuloendothelial system, the brown fat deposits, and skeletal muscle. Poliovirus probably accesses the CNS along peripheral nerves. Because poliovirus replicates in endothelial cells, the theory of viremic spread to the CNS was favored; however, poliovirus has almost never been cultured from the cerebrospinal fluid (CSF) of patients with paralytic disease, and patients with aseptic meningitis caused by poliovirus never have paralytic disease. With the first appearance of non-CNS symptoms, a secondary viremia probably occurs as a result of enormous viral replication in the reticuloendothelial system.

The exact mechanism of entry into the CNS is not known. Once entry is gained, however, the virus may traverse neural pathways, and multiple sites within the CNS are often affected. The effect on motor and vegetative neurons is most striking and correlates with the clinical manifestations. Perineuronal inflammation, a mixed inflammatory reaction with both polymorphonuclear leukocytes and lymphocytes, is associated with extensive neuronal destruction. Petechial hemorrhages and considerable inflammatory edema also occurs in areas of poliovirus infection. The poliovirus primarily infects motor neuron cells in the spinal cord (the anterior horn cells) and the medulla oblongata (the cranial nerve nuclei). Because of the overlap in muscle innervation by adjacent 2–3 segments of the spinal cord, clinical signs of weakness in the limbs develop when more than 50% of motor neurons are destroyed. In the medulla, less extensive lesions cause paralysis and involvement of

the reticular formation that contains the vital centers controlling respiration and circulation, which may have a catastrophic outcome. Involvement of the intermediate and dorsal horn and dorsal root ganglia in the spinal cord cause the typical hyperesthesia and myalgias that are seen in acute poliomyelitis. Other neurons affected are the nuclei in the roof and vermis of the cerebellum, the substantia nigra, and occasionally the red nucleus in the pons; there may be variable involvement of thalamic, hypothalamic, and pallidal nuclei and the motor cortex.

Apart from the histopathology of the CNS, inflammatory changes occur generally in the reticuloendothelial system. Inflammatory edema and sparse lymphocytic infiltration are prominently associated with hyperplastic lymphocytic follicles.

Infants acquire immunity transplacentally from their mothers; the immunity disappears at a variable rate during the first 4–6 mo of life. Active immunity after natural infection is probably lifelong but protects against the infecting serotype only; infections with other serotypes are possible. Poliovirus neutralizing antibodies develop within several days after exposure as a result of replication of the virus in the M cells in the intestinal tract and deep lymphatic tissues. This early production of circulating immunoglobulin (Ig) G antibodies protects against CNS invasion. Local (mucosal) immunity, conferred mainly by secretory IgA, is an important defense against subsequent re-infection of the gastrointestinal tract.

Clinical Manifestations.

The incubation period of poliovirus from contact to initial clinical symptoms is usually considered to be 8–12 days, with a range of 5–35 days. Poliovirus infections may follow one of several courses: inapparent infection, which occurs in 90–95% of cases and causes no disease and no sequelae; abortive poliomyelitis; nonparalytic poliomyelitis; or paralytic poliomyelitis. Paralysis, if it occurs, appears 3–8 days after the initial symptoms.

ABORTIVE POLIOMYELITIS.

In about 5% of patients, a nonspecific influenza-like syndrome occurs 1–2 wk after infection; this is termed abortive poliomyelitis. Fever, malaise, anorexia, and headache are prominent features, and there may be sore throat and abdominal or muscular pain. Vomiting occurs irregularly. The illness is short-lived (up to 2–3 days). The physical examination may be normal or may reveal nonspecific pharyngitis, abdominal or muscular tenderness, and weakness. Recovery is complete, and no neurologic signs or sequelae develop.

NONPARALYTIC POLIOMYELITIS.

In about 1% of all infected patients, the signs of abortive poliomyelitis are present but headache, nausea, and vomiting are more intense, and there is soreness and stiffness of the posterior muscles of the neck, trunk, and limbs. Fleeting paralysis of the bladder and constipation are frequent. Approximately two thirds of these children have a short symptom-free interlude between the first phase (**minor illness**) and the second phase (CNS disease or **major illness**). This two-phase course is less common in adults, in whom the evolution of symptoms is more insidious. Nuchal and spinal rigidity are the basis for the diagnosis of nonparalytic poliomyelitis during the second phase.

Physical examination reveals nuchal-spinal signs and changes in superficial and deep reflexes. In cooperative patients the nuchal-spinal signs are first sought by active tests. The patient is asked to sit up unassisted. If this causes undue effort and if the

knees flex upward and the patient writhes a bit from side to side in sitting up and uses the hands on the bed to assume the tripod supporting position, spinal rigidity is unmistakable. While sitting, the patient is asked to flex the chin to the chest and is observed for nuchal rigidity. Alternatively, in the supine position, with the knees held down gently, the patient is asked to sit up and kiss his or her knees. If the knees draw up sharply or if the maneuver cannot be adequately completed, there is stiffness of the spine, which is a result of muscle spasm. If the diagnosis is still uncertain or in infants, attempts should be made to elicit the Kernig and Brudzinski signs. Gentle forward flexion of the occiput and neck will elicit nuchal rigidity. Head drop is demonstrated by placing the hands under the patient's shoulders and raising the trunk. Although normally the head follows the plane of the trunk, in poliomyelitis it often falls backward limply but is not due to true paresis of the neck flexors. In struggling infants it may be difficult to distinguish voluntary resistance from clinically important true nuchal rigidity. One may place the infant's shoulders flush with the edge of the table, support the weight of the occiput in the hand, and then flex the head anteriorly. True nuchal rigidity will persist during this maneuver. When open, the anterior fontanel may be tense or bulging.

In the early stages the reflexes are normally active and remain so unless paralysis supervenes. Changes in reflexes, either increased or decreased, may precede weakness by 12–24?hr; hence, it is important to test reflexes, especially in nonparalytic patients managed at home. The superficial reflexes, the cremasteric and abdominal reflexes, and the reflexes of the spinal and gluteal muscles are usually the first to diminish. The spinal and gluteal reflexes may disappear before the abdominal and cremasteric reflexes. Changes in the deep tendon reflexes generally occur 8–24?hr after the superficial reflexes are depressed and indicate impending paresis of the extremities. Tendon reflexes are absent with paralysis. Sensory defects do not occur in poliomyelitis.

PARALYTIC POLIOMYELITIS.

Paralytic poliomyelitis develops in about 0.1% of persons infected with poliovirus, causing three clinically recognizable syndromes that represent a continuum of infection differentiated only by the portions of the CNS most severely affected. These are (1) spinal paralytic poliomyelitis, (2) bulbar poliomyelitis, and (3) polioencephalitis.

Spinal Paralytic Poliomyelitis. Spinal paralytic poliomyelitis may occur as the second phase of a biphasic illness, the first phase of which corresponds to abortive poliomyelitis. The patient then appears to recover and feels better for 2–5 days, after which severe headache and fever occur with exacerbation of the previous systemic

symptoms. Severe muscle pain is present and sensory and motor phenomena (e.g., paresthesia, hyperesthesia, fasciculations, and spasms) may develop. On physical examination the distribution of paralysis is characteristically spotty. Single muscles, multiple muscles, or groups of muscles may be involved in any pattern. Within 1–2 days, asymmetric flaccid paralysis or paresis occurs. Involvement of one leg is most common, followed by involvement of one arm. The proximal areas of the extremities tend to be involved to a greater extent than the distal areas. To detect mild muscular weakness, it is often necessary to apply gentle resistance in opposition to the muscle group being tested. Examination at this point may reveal nuchal stiffness or rigidity, muscle tenderness, initially hyperactive deep tendon reflexes (for a short period) followed by absent or diminished reflexes, and paresis or flaccid paralysis. In the spinal form there is weakness of some of the muscles of the neck, abdomen, trunk, diaphragm, thorax, or extremities. Sensation is intact; sensory disturbances, if present, suggest a disease other than poliomyelitis.

The paralytic phase of poliomyelitis is extremely variable; some patients progress during observation from paresis to paralysis, whereas others recover, which may be slow or rapid. The extent of paresis or paralysis is directly related to the extent of neuronal involvement; paralysis occurs if more than 50% of the neurons supplying the muscles are destroyed. The extent of involvement is usually obvious within 2–3 days; only rarely does progression occur beyond this interval. Paralysis of the lower limbs is often accompanied by bowel and bladder dysfunction ranging from transient incontinence to paralysis with constipation and urinary retention.

The onset and course of paralysis are variable and age-related. Infants and young children most frequently manifest the biphasic course, with prominent prodromal symptoms. Older persons may have a single phase in which prodromal symptoms and paralysis occur in a continuous fashion. In developing countries, where a history of intramuscular injections precedes paralytic poliomyelitis in about 50–60% of patients, patients may present initially with fever and paralysis without the characteristic biphasic course (**provocation paralysis**). The degree and duration of muscle pain are also variable; some patients have none, and others complain for days or weeks. Spasm and increased muscle tone with a transient increase in deep tendon reflexes occur in some patients, whereas in others flaccid paralysis may occur abruptly. Once the temperature returns to normal, no further paralytic manifestations are noted in most patients. Little recovery from paralysis is noted in the first days or weeks but, if it is to occur, is usually evident within 6 mo. The return of strength and reflexes is slow and may continue to improve as long as 18 mo after the acute disease. Lack of improvement from paralysis within the first several weeks or months after onset is usually evidence of permanent paralysis. Atrophy of the limb, failure of growth, and deformity is common and is especially evident in the growing child.

Bulbar Poliomyelitis. Bulbar poliomyelitis may occur as a clinical entity without apparent involvement of the spinal cord. Yet the infection is a continuum, and designation of the disease as bulbar implies only dominance of the clinical manifestations by dysfunctions of the cranial nerves and medullary centers. The clinical findings seen with bulbar poliomyelitis with respiratory difficulty (other than paralysis of extraocular, facial, and masticatory muscles) include (1) nasal twang to the voice or cry caused by palatal and pharyngeal weakness (hard-consonant words such as “cookie” or “candy” bring this out best); (2) inability to swallow smoothly, resulting in accumulation of saliva in the pharynx, indicates partial immobility (holding the larynx lightly and asking the patient to swallow will confirm such immobility); (3) accumulated pharyngeal secretions, which may cause irregular respirations because each inspiration must be “planned” to avoid aspirating; the respirations may thus appear interrupted and abnormal even to the point of falsely simulating intercostal or diaphragmatic weakness; (4) absence of effective coughing, shown by constant fatiguing efforts to clear the throat; (5) nasal regurgitation of saliva and fluids as a result of palatal paralysis, with inability to separate the oropharynx from the nasopharynx during swallowing; (6) deviation of the palate, uvula, or tongue; (7) involvement of vital centers in the medulla, which are manifested by irregularities in rate, depth, and rhythm of respiration; by cardiovascular alterations including blood pressure changes (especially increased blood pressure), alternate flushing and mottling of the skin, and cardiac arrhythmias; and by rapid changes in body temperature; (8) paralysis of one or both vocal cords, causing hoarseness, aphonia, and ultimately asphyxia unless this is recognized by laryngoscopy and managed by immediate tracheostomy; and (9) **the rope sign,** an acute angulation between the chin and larynx caused by weakness of the hyoid muscles (the hyoid bone is pulled posteriorly, narrowing the hypopharyngeal inlet).

Uncommonly, bulbar disease may culminate in an ascending paralysis (Landry type), in which there is progression cephalad from initial involvement of the lower extremities. Hypertension and other autonomic disturbances are common in bulbar involvement and may persist for a week or more or may be transient.

Occasionally, hypertension is followed by hypotension and shock and is associated with irregular or failed respiratory effort, delirium, or coma. This kind of bulbar disease may be rapidly fatal.

The course of bulbar disease is variable; some patients die as a result of extensive, severe involvement of the various centers in the medulla; others recover partially but require ongoing respiratory support, and others recover completely. Cranial nerve involvement is seldom permanent. Atrophy of muscles may be evident, patients immobilized for long periods may develop pneumonia, and renal stones may form as a result of hypercalcemia and hypercalciuria secondary to bone resorption.

Polioencephalitis. Polioencephalitis is a rare form of the disease in which higher centers of the brain are severely involved. Seizures, coma, and spastic paralysis with increased reflexes may be observed. Irritability, disorientation, drowsiness, and coarse tremors not explained by inadequate ventilation are noted; peripheral or cranial nerve paralysis coexists or ensues. Hypoxia and hypercapnia caused by inadequate ventilation due to respiratory insufficiency may produce disorientation without true encephalitis. The manifestations are common to encephalitis of any cause and can only be attributed to polioviruses by specific viral diagnosis or if accompanied by flaccid paralysis.

Paralytic Poliomyelitis with Ventilatory Insufficiency. A number of components acting together may produce ventilatory insufficiency resulting in hypoxia and hypercapnia, which may produce profound effects on many other systems. Because respiratory insufficiency may develop rapidly, close continued clinical evaluation is

essential. Despite weakness of the respiratory muscles, the patient may respond with so much respiratory effort (associated with anxiety and fear) that overventilation may occur at the outset, resulting in respiratory alkalosis. Such effort is fatiguing and contributes to respiratory failure.

There are certain characteristic patterns of disease. Pure spinal poliomyelitis with respiratory insufficiency involves tightness, weakness, or paralysis of the respiratory muscles (chiefly the diaphragm and intercostals) without discernible clinical involvement of the cranial nerves or vital centers that control respiration, circulation, and body temperature. The cervical and thoracic spinal cord segments are chiefly affected. Pure bulbar poliomyelitis involves paralysis of the motor cranial nerve nuclei with or without involvement of the vital centers. Involvement of the 9th, 10th, and 12th cranial nerves results in paralysis of the pharynx, tongue, and larynx with consequent airway obstruction. Bulbospinal poliomyelitis with respiratory insufficiency affects the respiratory muscles and results in coexisting bulbar paralysis.

The clinical findings associated with involvement of the respiratory muscles include (1) anxious expression; (2) inability to speak without frequent pauses, resulting in short, jerky, “breathless” sentences; (3) increased respiratory rate; (4) movement of the ala nasi and of the accessory muscles of respiration; (5) inability to cough or sniff with full depth; (6) paradoxical abdominal movements caused by diaphragmatic immobility due to spasm or weakness of one or both leaves; and (7) relative immobility of the intercostal spaces, which may be segmental, unilateral, or bilateral. When the arms are weak, and especially when deltoid paralysis occurs, there may be impending respiratory paralysis because the phrenic nerve nuclei are in adjacent areas of the spinal cord. Observation of the patient's capacity for thoracic breathing while the abdominal muscles are splinted manually indicates minor degrees of paresis. Light manual splinting of the thoracic cage will help to assess the effectiveness of diaphragmatic movement.

Diagnosis.

Poliomyelitis should be considered in any unimmunized or incompletely immunized child with nonspecific febrile illness, aseptic meningitis, or paralytic disease. VAPP should be considered in any child with paralytic disease occurring 7–14 days after receiving oral poliovirus vaccine. VAPP can occur at later times after administration, and should be considered in any child with paralytic disease in countries or regions where wild type poliovirus has been eradicated and OPV has been administered to the child or a contact. The combination of fever, headache, neck and back pain, asymmetric flaccid paralysis without sensory loss, and pleocytosis does not regularly occur in any other illness.

The World Health Organization (WHO) currently recommends that the laboratory diagnosis of poliomyelitis be confirmed by isolation and identification of poliovirus in the stool, with specific identification of wild-type and vaccine type strains. In suspected cases of acute flaccid paralysis, 2 stool specimens should be collected 24–48?hr apart, as soon as possible after the diagnosis of poliomyelitis is suspected. Poliovirus concentrations are high in the stool in the first week after the onset of paralysis, which is the optimal time for collection of stool specimens. Polioviruses may be isolated from 80 to 90% of acutely ill patients, whereas less than 20% may yield virus within 3–4 wk after onset of paralysis. Because most children with spinal or bulbospinal poliomyelitis have constipation, rectal straws may be used to obtain specimens; ideally a minimum of 8–10 grams should be collected. In laboratories that can isolate poliovirus, isolates should be sent to either the Centers for Disease Control and Prevention or to one of the WHO-certified poliomyelitis laboratories where DNA sequence analysis can be performed to distinguish between wild poliovirus and neurovirulent, revertant oral poliovirus vaccine strains. With the current WHO global plan for eradication of poliomyelitis worldwide, most regions of the world (the Americas, Europe, and Australia) have been certified wild-poliovirus free; in these areas, poliomyelitis is most often caused by vaccine strains. Hence it is critical to differentiate between wild type and revertant vaccine type strains.

The CSF, while often normal during the minor illness, demonstrates a pleocytosis between 20 and 300 cells/mm^3 with CNS involvement; the cells in the CSF may be polymorphonuclear early in the disease but shift to mononuclear cells soon afterward. By the second week of the major illness, the CSF cell count falls to near-normal values. In contrast, the CSF protein is normal or only slightly elevated at the outset of CNS disease but usually rises to between 50–100?mg/dL by the second week of illness. In polioencephalitis the CSF may remain normal or show minor changes. Serologic testing demonstrates seroconversion or a fourfold or greater increase in antibody titers, when measured during the acute phase of illness and 3–6 wk later.

DIFFERENTIAL DIAGNOSIS.

Poliomyelitis should be considered in the differential diagnosis of any case of paralysis, and is only one of many causes of acute flaccid paralysis in children and adults. The possibility of polio should be considered in any case of acute flaccid paralysis even in countries where polio has been eradicated. The diagnoses most often confused with polio are the Guillain-Barré syndrome, transverse myelitis, and traumatic paralysis due to sciatic nerve injury. In Guillain-Barré syndrome, which is the most difficult to distinguish from poliomyelitis, the paralysis is characteristically symmetric and sensory changes and pyramidal tract signs are common; these are absent in poliomyelitis. Fever, headache, and meningeal signs are less notable, and there are few cells but an elevated protein level in the CSF. Transverse myelitis progresses rapidly over hours to days, causing an acute symmetric paralysis of the lower limbs with concomitant anesthesia and diminished sensory perception. Autonomic signs of hypothermia in the affected limbs are common, and there is bladder dysfunction. The CSF is usually normal. Traumatic neuritis occurs from a few hours to a few days after the traumatic event, is asymmetric, acute, and affects only one limb. There is reduced or absent muscle tone and deep tendon reflects in the affected limb with pain in the gluteus. The CSF is normal.

There are numerous other causes of acute flaccid paralysis (Table 228–1). In most conditions, the clinical features are sufficient to differentiate between these various causes, but in

TABLE 228-1 -- **Differential Diagnosis of Acute Flaccid Paraly**

Site, Condition, Factor, or Agent	Clinical Findings	Onset of Paralysis	Progression of Paralysis	Sensory Signs and Symptoms
Anterior Horn Cells of Spinal Cord				
Poliomyelitis (Wild and VAPP)	Paralysis	Incubation period 7–14 days (4–35 days)	24–48?hr to onset of full paralysis; proximal > distal, asymmetric	No
Nonpolio enterovirus	Hand-foot-and-mouth disease, aseptic meningitis, AHC	As in poliomyelitis	As in poliomyelitis	No
Other Neurotropic Viruses				
Rabies virus		Months to years	Acute, symmetric, ascending	Yes
Varicella-zoster virus	Exanthematous vesicular eruptions	Incubation period 10–21 days	Acute, symmetric, ascending	Yes
Japanese encephalitis virus		Incubation period 5–15 days	Acute, proximal, asymmetric	+/-
Guillain-Barré Syndrome				
Acute inflammatory polyradiculoneuropathy	Preceding infection, bilateral facial weakness	Hours to 10 days	Acute, symmetric, ascending (days to 4 wk)	Yes
Acute motor axonal neuropathy	Fulminant, widespread paralysis, bilateral facial weakness, tongue involvement	Hours to 10 days	1–6 days	No
Acute Traumatic Sciatic Neuritis				
Intramuscular gluteal injection	Acute, asymmetrical	Hours to 4 days	Complete, affected limb	Yes
Acute transverse myelitis	Preceding *Mycoplasma pneumoniae, Schistosoma*, other parasitic or viral infection	Acute, symmetric hypotonia of lower limbs	Hours to days	Yes
Epidural abscess	Headache, back pain, local spinal tenderness, meningismus	Complete		Yes
Spinal cord compression; trauma		Complete	Hours to days	Yes
Neuropathies				
Exotoxin of *Corynebacterium diphtheriae*	In severe cases, palatal paralysis, blurred vision	Incubation period 1–8 wk (paralysis 8–12 wk after onset of illness)		Yes
Toxin of *Clostridium botulinum*	Abdominal pain, diplopia, loss of accommodation, mydriasis	Incubation period 18–36?hr	Rapid, descending, symmetric	+/-
Tick bite paralysis	Ocular symptoms	Latency period 5–10 days	Acute, symmetric, ascending	No
Diseases of the Neuromuscular Junction				
Myasthenia gravis	Weakness, fatigability, diplopia, ptosis, dysarthria		Multifocal	No
Disorders of Muscle				
Polymyositis	Neoplasm, autoimmune disease	Subacute, proximal > distal	Weeks to months	No
Viral myositis		Pseudoparalysis	Hours to days	No
Metabolic Disorders				
Hypokalemic periodic paralysis		Proximal limb, respiratory muscles	Sudden postprandial	No
ICU Weakness				
Critical illness polyneuropathy	Flaccid limbs and respiratory weakness	Acute, following SIRS/sepsis	Hours to days	+/-

AHC = acute hemorrhagic conjunctivitis; ICU = intensive care unit; SIRS = systemic inflammatory r

Modified from Marx A, Glass JD, Sutter RW: ifferential diagnosis of acute flaccid paralysis and its r Epidemiol Rev 2000;22:298–316.

some cases nerve conduction studies and electromyograms in addition to muscle biopsies may be required.

Conditions causing pseudoparalysis do not present with nuchal-spinal rigidity or pleocytosis. These causes include unrecognized trauma, transient (toxic) synovitis, acute osteomyelitis, acute rheumatic fever, scurvy, and congenital syphilis (pseudoparalysis of Parrot).

Treatment.

Inasmuch as there are no specific antiviral agents for treating poliomyelitis, the management is supportive and aimed at limiting progression of disease, prevention of ensuing skeletal deformities, and preparation of the child and family for prolonged treatment required and for permanent disability if this seems likely. Patients with the nonparalytic and mildly paralytic forms of poliomyelitis may be treated at home. All intramuscular injections and surgical procedures are contraindicated during the acute phase of the illness, especially in the first week of illness, because these may result in progression of disease.

ABORTIVE POLIOMYELITIS.

Supportive treatment with analgesics, sedatives, an attractive diet, and bed rest until the child's temperature is normal for several days is usually sufficient. Avoidance of exertion for the ensuing 2 wk is desirable, and there should be careful neurologic and musculoskeletal examinations 2 mo later to detect any minor involvement.

NONPARALYTIC POLIOMYELITIS.

Treatment for the nonparalytic form is similar to that for the abortive form; in particular, relief is indicated for the discomfort of muscle tightness and spasm of the neck, trunk, and extremities. Analgesics are more effective when they are combined with the application of hot packs for 15–30?min every 2–4?hr. Hot tub baths are sometimes useful. A firm bed is desirable and can be improvised at home by placing table leaves or a sheet of plywood beneath the mattress. A footboard or splint should be used to keep the feet at a right angle to the legs. Because muscular discomfort and spasm may continue for some weeks, even in the nonparalytic form, hot packs and gentle physical therapy may be necessary. Such patients should also be carefully examined 2 mo after apparent recovery to detect minor residual effects that might cause postural problems in later years.

PARALYTIC POLIOMYELITIS.

Most patients with the paralytic form require hospitalization, and complete physical rest in a calm atmosphere is desirable for the first 2–3 weeks. Suitable body alignment is necessary for comfort and to avoid excessive skeletal deformity. A neutral position with the feet at a right angle to the legs, knees slightly flexed, and hips and spine straight is achieved by use of boards, sandbags, and, occasionally, light splint shells. The position should be changed every 3–6?hr. Active and passive motions are indicated as soon as the pain has disappeared. Moist hot packs may relieve muscle pain and spasm. Opiates and sedatives are permissible only if no impairment of ventilation is present or impending. Constipation is common, and fecal impaction should be prevented. When bladder paralysis occurs, a parasympathetic stimulant such as bethanechol may induce voiding in 15–30?min; some patients do not respond, and others respond with nausea, vomiting, and palpitations. Bladder paresis rarely lasts more than a few days. If bethanechol fails, manual compression of the bladder and the psychologic effect of running water should be tried. If catheterization must be performed, care must be taken to prevent urinary tract infections. An appealing diet and a relatively high fluid intake should be started at once unless the patient is vomiting. Additional salt should be provided if the environmental temperature is high or if the application of hot packs induces sweating. Anorexia is common initially. Adequate dietary and fluid intake can be maintained by placement of a central venous catheter. An orthopedist and a physiatrist should see these patients as early in the course of the illness as possible and should assume responsibility for their care before fixed deformities develop.

The management of pure bulbar poliomyelitis consists of maintaining the airway and avoiding all risk of inhalation of saliva, food, or vomitus. Gravity drainage of accumulated secretions is favored by using the head-low (foot of bed elevated 20–25 degrees) prone position with the face to one side. Patients with weakness of the muscles of respiration or swallowing should be nursed in a lateral or semi-prone position. Aspirators with rigid or semirigid tips are preferred for direct oral and pharyngeal aspiration, and soft, flexible catheters may be used for nasopharyngeal aspiration. Fluid and electrolyte equilibrium is best maintained by intravenous infusion because tube or oral feeding in the first few days may incite vomiting. In addition to close observation for respiratory insufficiency, the blood pressure should be taken at least twice daily because hypertension is not uncommon and occasionally leads to hypertensive encephalopathy. Patients with pure bulbar poliomyelitis may require tracheostomy because of vocal cord paralysis or constriction of the hypopharynx; most patients who recover have little residual impairment, although some exhibit mild dysphagia and occasional vocal fatigue with slurring of speech.

Impaired ventilation must be recognized early; mounting anxiety, restlessness, and fatigue are early indications for preemptive intervention. Tracheostomy is indicated for some patients with pure bulbar poliomyelitis, spinal respiratory muscle paralysis, and bulbospinal paralysis because these patients are generally unable to cough, sometimes for many months. Mechanical respirators are often needed.

Complications.

Paralytic poliomyelitis may be associated with numerous complications. Melena severe enough to require transfusion may result from single or multiple superficial intestinal erosions; perforation is rare. Acute gastric dilatation may occur abruptly during the acute or convalescent stage, causing further respiratory embarrassment; immediate gastric aspiration and external application of ice bags are indicated. Mild

hypertension of a few days' or weeks' duration is common in the acute stage, probably related to lesions of the vasoregulatory centers in the medulla and especially to underventilation. In the later stages, because of immobilization, hypertension may occur along with hypercalcemia, nephrocalcinosis, and vascular lesions. Dimness of vision, headache, and a lightheaded feeling associated with hypertension should be regarded as premonitory of a frank convulsion. Cardiac irregularities are uncommon, but electrocardiographic abnormalities suggesting myocarditis are not rare. Acute pulmonary edema occurs occasionally, particularly in patients with arterial hypertension. Pulmonary embolism is uncommon despite the immobilization. Hypercalcemia occurs due to skeletal decalcification that begins soon after immobilization and results in hypercalciuria, which in turn predisposes the patient to urinary calculi, especially when urinary stasis and infection are present. A high fluid intake is the only effective prophylactic measure.

Prognosis.

The outcome of inapparent, abortive poliomyelitis and aseptic meningitis syndromes is uniformly good, with death being exceedingly rare and with no long-term sequelae. The outcome of paralytic disease is determined primarily by degree and severity of CNS involvement. In severe bulbar poliomyelitis, the mortality may be as high as 60%, whereas in less severe bulbar involvement and/or spinal poliomyelitis, mortality varies from 5 to 10%, generally from causes other than the poliovirus infection.

Maximum paralysis usually occurs 2–3 days after the onset of the paralytic phase of the illness, with stabilization followed by gradual return of muscle function. The recovery phase lasts usually about 6 mo, beyond which persisting paralysis is permanent. Male children but female adults, generally, are more likely to develop paralysis. Mortality and the degree of disability are greater after the age of puberty. Pregnancy is associated with an increased risk of paralytic disease. Tonsillectomy and intramuscular injections may enhance the risk of acquisition of bulbar or localized disease, respectively. Increased physical activity,

exercise, and fatigue during the early phase of illness have been cited as factors leading to an increased risk of paralytic disease. Finally it has been clearly demonstrated that type 1 poliovirus has the greatest propensity for natural poliomyelitis and type 3 for VAPP.

Postpolio Syndrome. After an interval of 30–40 years, as many as 30–40% of persons who survived paralytic poliomyelitis in childhood may experience muscle pain and exacerbation of existing weakness, or they may develop new weakness or paralysis. This entity, which is referred to as postpolio syndrome, has been reported only in persons who were infected in the era of wild poliovirus circulation. Risk factors for postpolio syndrome include increasing length of time since acute poliovirus infection, presence of permanent residual impairment after recovery from acute illness, and female sex.

Prevention.

Vaccination is the only effective method of preventing poliomyelitis. Hygienic measures help limit the spread of the infection among young children, but immunization is necessary to control transmission among all age groups. Both the inactivated polio vaccine (IPV), which is currently produced using improved methods compared with the original vaccine and is sometimes referred to as enhanced IPV, and the live, attenuated, orally administered polio vaccine (OPV) have established efficacy in preventing poliovirus infection and paralytic poliomyelitis. Both vaccines induce production of antibodies against the three strains of poliovirus. IPV elicits higher serum IgG antibody titers, but OPV also induces significantly greater mucosal IgA immunity in the oropharynx and gastrointestinal tract that limits replication of the wild poliovirus at these sites. Transmission of wild poliovirus by fecal spread is limited in OPV recipients. The immunogenicity of IPV is not affected by the presence of maternal antibodies and IPV has no adverse effects. Live vaccine may undergo reversion to neurovirulence as it multiplies in the human intestinal tract and may cause VAPP in vaccinees or in their contacts. The overall risk for recipients is 1 case/6.2 million doses. As of January 2000, the IPV-only schedule is recommended for routine polio vaccination in the United States. All children should receive four doses of IPV at 2 mo, 4 mo, 6–18 mo, and 4–6 yr of age.

In 1988, the World Health Assembly resolved to eradicate poliomyelitis globally by 2000, and remarkable progress has been made toward reaching this target. To achieve this, the WHO used four basic strategies: routine immunization, National Immunization Days (NIDs), Acute Flaccid Paralysis surveillance, and mopping up immunization. The oral polio vaccine is the only vaccine recommended by WHO for eradication. By the end of 1999, at least one set of NIDs had been conducted in every polio endemic country in the world. This strategy has resulted in a greater than 99% decline in poliomyelitis cases; as of February 2002, there are only 10 countries in the world endemic for poliomyelitis. Globally there were 542 cases of polio, of which 478 were confirmed as wild virus. Given this rapid progress, planning has begun for the “end game” for the global polio eradication initiative. The main concerns are the containment of laboratory stocks of poliovirus (since the risk of inadvertent transmission of poliovirus from a laboratory to the community is possible) and the circulation of vaccine-derived polioviruses (VDPVs). As long as OPV is being used, there is the potential that circulating VDPVs will acquire the neurovirulent and transmission characteristics of the wild type polioviruses; indeed, this occurred in Egypt in 1993, Hispaniola during 2000 to 2001, and in the Philippines in 2001. Poor vaccination coverage appeared to be the major risk factor for circulating VDPVs. There is also concern that immune-deficient persons can act as long-term poliovirus carriers and pose a threat of reseeding the population. There are no long-term carriers identified yet in developing countries, and overall 12 have been identified worldwide who have excreted poliovirus for more than 6 mo, only 4 of whom are currently excreting virus. HIV has not been found to be a cause for long-term excretion of virus.

Currently there are 10 countries that are global priorities because they face challenges in eradication. The Indian subcontinent, Nigeria, Ethiopia, and the Democratic Republic of Congo are considered poliovirus reservoirs where transmission is particularly intense due to dense populations, low immunization coverage, and poor sanitation. The second major category is those afflicted by

conflict where implementation of vaccination and surveillance activities is challenging (e.g., Afghanistan, Angola, Somalia, and Sudan). All these countries require multi-level eradication activities, but they pose a problem to surrounding countries because wild type poliovirus can be imported from these countries to countries where immunization rates have dropped (but have been declared poliomyelitis free) such as China and Bulgaria. Hence to achieve global eradication, intensified activities are being conducted in all the remaining identified countries. Once eradication has been achieved, which is conceivable in the near future, there are 3 possible strategies: (1) coordinated discontinuation of OPV use worldwide; (2) replacement of OPV with IPV; and (3) development of new live vaccines that would not cause VAPP and that are not transmittable. Obviously the first strategy would be the most desirable but the debate continues and the main concerns are that a VDPV circulation may continue, especially if other enteroviruses recombine with OPV. Because the whole genetic structure of poliovirus is known, it would be easy to genetically reconstruct poliovirus for use in bioterrorism. Until such time as this decision is reached, in countries where the risk for VAPP is higher than the risk of transmission of poliomyelitis, the injectable poliovirus vaccines continue to confer immunity and are being used routinely, and in other countries that either cannot afford IPV or where transmission is endemic, the OPV will continue to be used both in routine immunization as well as in the NIDs strategy.

Chapter 229 - Nonpolio Enteroviruses*

Mark J. Abzug

The genus *Enterovirus* contains a large number of viral agents that produce a broad range of clinically important illnesses. The genus name reflects the importance of the gastrointestinal tract as the primary source for transmission and primary site of viral invasion and replication. However, viremic spread to distant sites accounts for the majority of clinical manifestations associated with the enteroviruses.

*Includes text from the Enteroviruses chapter written by Abraham Morag and Pearay L. Ogra from the 16th edition.

Etiology.

Enteroviruses are non-enveloped, single-stranded, positive-sense viruses in the Picornaviridae family, so-named because they are small RNA-containing viruses. Other members of this family include the genus *Rhinovirus*, the genus *Hepatovirus* (hepatitis A virus), and genera containing related animal viruses. The original enterovirus subgroups—polioviruses (Chapter 228), coxsackieviruses, and echoviruses—were differentiated by their replication patterns in tissue culture and animals (Box 229–1). Coxsackieviruses derive their name from Coxsackie, New York, where they were discovered; echoviruses reflect an acronym applied to a group of viruses originally without disease associations (*e*—enteric, *c*—cytopathic, *h*—human, *o*—orphan *viruses*). Newer enteroviruses are classified by numbering. Serotypes (species) are distinguished by antigenic differences. Although more than 60 different serotypes have been identified, 11 account for the majority of disease. No enterovirus disease is uniquely associated with any specific serotype; however, certain manifestations are preferentially associated with specific serotypes.

Epidemiology.

Enterovirus infections are very common and have a worldwide distribution. In temperate climates, they have a distinct seasonality, with an annual epidemic peak in summer and fall. Some transmission does occur year-round, however. Enteroviruses have been found to be responsible for 33–65% of acute febrile illnesses and 55–65% of hospitalizations for suspected sepsis in infants during the summer and fall in the United States, and 25% year-round. In tropical and semitropical areas, enteroviruses frequently circulate all year-round. In general, only a few serotypes circulate simultaneously. Infections by different serotypes in the same child can occur within the same season. Factors associated with increased incidence and/or severity of enterovirus infection include young age, male sex, poor hygiene, overcrowding, and low socioeconomic status; more than 25% of symptomatic enterovirus infections occur in children younger than 1 yr of age. Breast-feeding reduces the risk of infection in infants.

Humans are the only known reservoir for the human enteroviruses. Virus is spread person-to-person by the fecal-oral and respiratory routes and vertically, from mother to neonate, either prenatally or in the peripartum period. Enteroviruses can survive on environmental surfaces, permitting transmission via fomites. Enteroviruses also can frequently be isolated from sewage and can survive for months in wet soil, but person-to-person spread is the primary mode of transmission. Environmental contamination is likely the result of, rather than the cause for, human infection. Transmission occurs within families with young children (>50% spread to susceptible household contacts), daycare centers, playgrounds, summer camps, orphanages, and hospital nurseries; severe secondary infections may occur in nursery outbreaks. Diaper changing is a risk factor for spread, whereas handwashing decreases transmission.

Box 229-1. Classification of Human Enteroviruses

Family:	Picornaviridae
Genus:	Enterovirus
Subgroups:	Poliovirus serotypes 1–3
	Coxsackie A virus serotypes A1–A22, A24 (A23 reclassified as echovirus 9)
	Coxsackie B virus serotypes B1–B6
	Echovirus serotypes 1–9, 11–27, 29–33 (echoviruses 10 and 28 reclassified as non-enteroviruses; echovirus 34 reclassified as coxsackievirus

	and 28 reclassified as non-enteroviruses; echovirus 34 reclassified as coxsackievirus A24; echoviruses 22 and 23 may be reclassified to a separate genus designated parenteroviruses)
	Numbered enterovirus serotypes 68–71 (enterovirus 72 reclassified as hepatitis A virus; a new serotype, enterovirus 73, has recently been proposed)

Large outbreaks of enterovirus infections can occur. Outbreaks of hand-foot-and-mouth disease associated with severe central nervous system (CNS) and/or cardiopulmonary disease due to enterovirus 71 have occurred in recent years in Malaysia, Japan, Taiwan, and Australia; outbreaks of acute hemorrhagic conjunctivitis due to enterovirus 70 and coxsackievirus A24 have occurred in India and tropical regions; and community outbreaks of enterovirus meningitis have been reported. Modern molecular tools such as reverse transcription polymerase chain reaction (RT-PCR), restriction fragment length polymorphism (RFLP) analysis, single-strand conformation polymorphism (SSCP) analysis, and genomic sequencing have been used to rapidly identify outbreaks, demonstrate commonality of outbreak strains, and detect differences between epidemic strains and older prototype strains. Such analyses have demonstrated that enteroviruses undergo genetic drift that can lead to changes in antigenicity.

The incubation period of enterovirus infections is typically 3–6 days, except for acute hemorrhagic conjunctivitis, which has a shorter incubation period of 1–3 days. Infected children, both symptomatic and asymptomatic, frequently shed enteroviruses from the respiratory tract for less than 1–3 wk, whereas fecal shedding continues from several weeks up to 8 wk postinfection.

Pathogenesis.

Following acquisition of virus by the oral or respiratory route, initial viral replication occurs in the pharynx and intestine, possibly within mucosal M cells. The absence of an envelope favors survival of enteroviruses in the harsh conditions of the gastrointestinal tract. Cell surface macromolecules, including poliovirus receptor (PVR), integrin VLA-2, decay accelerating factor complement regulatory protein (DAF/CD55), intercellular adhesion molecule-1 (ICAM-1), and coxsackievirus-adenovirus receptor, serve as receptors in the gastrointestinal tract for enteroviruses. Two or more enteroviruses may invade and replicate in the gastrointestinal tract at the same time, but replication of one type often interferes with growth of the heterologous type (interference).

After an enterovirus attaches to its cell surface receptor, a conformational change in surface capsid proteins facilitates penetration into the cell and release of viral RNA in the cytoplasm (uncoating). Translation of the positive-sense RNA ensues, resulting in synthesis of a polyprotein that undergoes sequential cleavage by proteinases encoded in the polyprotein. Several proteins produced then guide synthesis of negative-sense RNA that serves as a template for replication of new positive-sense RNA. The genome is approximately 7500 nucleotides long and includes a highly conserved 5' non-coding region important for replication efficiency and a 3' polyA region, also highly conserved, that flank a continuous region that encodes viral proteins. The 5' end is covalently linked to a small viral protein (VPg) necessary for initiation of RNA synthesis. There is significant variation in the genomic regions encoding the structural proteins (with corresponding variability in antigenicity). Replication is followed by further cleavage of proteins and assembly of the genome and the viral capsid into 30-nm icosahedral virions. Of the 4 structural proteins in the viral capsid, VP1-VP4 (additional regulatory proteins such as an RNA-dependent RNA polymerase and proteases are also present in the virion), VP1 is the most important determinant of serotype specificity. Approximately 10^4 –10^5 virions are released from an infected cell by lysis within 5–10?hr of infection.

The presumed pathogenesis of enterovirus infections beyond the gastrointestinal tract is largely based on studies of animal models. Initial replication in the pharynx and intestine is followed within days by multiplication in lymphoid tissue such as tonsils, Peyer patches, and regional lymph nodes. A primary, transient viremia (**minor viremia**) results in spread to more distant parts of the reticuloendothelial system including the liver, spleen, bone marrow, and distant lymph nodes. Host immune responses may limit replication and progression beyond the

reticuloendothelial system, resulting in subclinical infection. Clinical infection occurs if replication proceeds in the reticuloendothelial system and virus spreads via a secondary, sustained viremia (**major viremia**) to target organs such as the CNS, heart, and skin. Tropism to target organs is determined in part by the infecting serotype.

Enteroviruses can damage a wide variety of organs and systems, including the CNS, heart, liver, lungs, pancreas, kidneys, muscle, and skin. Damage is mediated both by local necrosis and the host inflammatory response. Central nervous system infections are often associated with mononuclear pleocytosis of the cerebrospinal fluid (macrophages and activated T lymphocytes) and a mixed meningeal inflammatory response. Parenchymal involvement may occur at multiple sites, including cerebral white and gray matter, cerebellum, basal ganglia, brainstem, and spinal cord; perivascular and parenchymal mixed or lymphocytic inflammation, perivascular lymphocytic cuffing, gliosis, cellular degeneration, and neuronophagocytosis may be present. Encephalitis during recent outbreaks of enterovirus 71 has been characterized by severe brainstem and spinal cord involvement. Myocarditis is characterized by perivascular and interstitial mixed

inflammatory infiltrates and myocyte damage. Chronic inflammation may persist after virus has been cleared.

Severe neonatal infections can manifest hepatic necrosis with variable inflammation; myocardial mixed inflammatory infiltrates, edema, and necrosis; meningeal and brain inflammation, hemorrhage, gliosis, and necrosis; pulmonary inflammation, hemorrhage, and thrombosis; pancreatic inflammation and necrosis; adrenal inflammation, hemorrhage, infarct, and necrosis; and disseminated intravascular coagulation.

Possible persistent infection by enteroviruses, especially coxsackie B viruses, has been implicated in dilated cardiomyopathy. Enteroviral RNA sequences and/or antigens have been demonstrated in a significant percentage of cardiac tissues in some series. Other studies, however, have failed to confirm a significant association. Persistent enterovirus infection has also been implicated in other conditions such as chronic fatigue syndrome and amyotrophic lateral sclerosis. An etiologic role in these syndromes awaits definitive proof.

Infection by coxsackie B viruses, coxsackie A viruses, and echoviruses has also been implicated in the pathogenesis of type I (insulin-dependent) diabetes mellitus. These viruses can induce ß cell damage in mice, and reports of human infection in utero or in early childhood in temporal relation to development of clinical diabetes or laboratory evidence of a prediabetic state suggest a possible link. Other evidence includes detection of enteroviral RNA in diabetic or prediabetic children and demonstration of altered immune responses to enteroviruses in patients with diabetes. Finally, in rare cases, enteroviruses have been recovered from affected pancreases. Enteroviruses have also been suggested as contributors to other autoimmune diseases such as Graves disease.

Development of circulating type-specific neutralizing antibodies appears to be the most important aspect of the immune response mediating prevention against and recovery from enterovirus infections. IgM antibodies, followed by long-lasting IgA and IgG antibodies, are produced. Mucosal immunity, conferred mainly by secretory IgA, is also an important defense, conferring protection against intestinal re-infection. Although local re-infection of the gastrointestinal tract can occur, replication is usually limited and not associated with disease. Evidence also suggests that cellular defenses (especially macrophage function) play an important role in recovery from infection. Altered T-lymphocyte responses to enterovirus 71 were associated with severe meningoencephalitis during recent epidemics.

Antibody deficiency states, including hypogammaglobulinemia and agammaglobulinemia, predispose to severe, often chronic enterovirus infections. Similarly, perinatally infected neonates who lack maternal type-specific antibody to the infecting virus are at risk for severe clinical disease. Other risk factors for significant enterovirus illness include young age, immune suppression (e.g., post-transplantation), and, according to animal model studies and/or epidemiologic observations, exercise, cold exposure, malnutrition, and pregnancy.

Clinical Manifestations.

The clinical manifestations of enterovirus infections are protean, ranging from asymptomatic infection or undifferentiated febrile or respiratory illnesses in the majority, to, less frequently, severe diseases such as meningoencephalitis, myocarditis, and neonatal sepsis. Symptomatic disease is generally more frequent in young children.

ASYMPTOMATIC INFECTION.

A large percentage of enterovirus infections are asymptomatic. A majority of individuals shedding virus are asymptomatic or had very mild illness, yet may serve as a significant source for spread of infection.

NONSPECIFIC FEBRILE ILLNESS.

Nonspecific febrile illnesses are the most common symptomatic manifestations of enterovirus infections, and are especially frequent in infants and young children. In addition to being problematic for the symptoms they cause, they are difficult to clinically differentiate from serious infections such as bacteremia and bacterial meningitis and therefore prompt diagnostic testing, presumptive therapy, and hospitalizations for suspected bacterial infection in young infants.

Illness usually begins with abrupt onset of fever, usually 38.5–40°C (101–104°F), with accompanying malaise and irritability. Other symptoms may include lethargy, anorexia, diarrhea, nausea and vomiting, abdominal discomfort, rash, sore throat, and respiratory symptoms. In older children, headache and myalgia frequently also occur. Findings on examination are generally nonspecific and may include mild conjunctivitis, mild injection of the pharynx, and cervical lymphadenopathy. Meningitis may be present but, in infants, specific clinical features distinguishing those with and without meningitis are often lacking. Fever lasts a mean of 3 days. Occasionally fever is biphasic; it is present for 1 day, absent for 2–3 days, then recurs for an additional 2–4 days. Duration of illness is usually 4–7 days but can range from 1 day to longer than 1 wk. White blood cell count and other routine laboratory tests are generally normal. Concomitant enterovirus and bacterial infection has been observed in a small number of infants.

Enterovirus illnesses may be associated with a wide variety of skin manifestations. In general, the frequency is inversely related to age. Some serotypes commonly associated with rashes are echoviruses 9, 11, 16, and 25; coxsackie A viruses 2, 4, 9, and 16; and coxsackie B viruses 3–5. Rashes vary widely in their characteristics and include macular, maculopapular, urticarial, vesicular, and petechial eruptions. Virus can occasionally be recovered from vesicular skin lesions. Fever and rash illnesses caused by enteroviruses may mimic other infections such as meningococcemia, measles, and rubella.

HAND-FOOT-AND-MOUTH DISEASE.

Hand-foot-and-mouth disease is one of the more distinctive rash syndromes caused by enteroviruses. It is most frequently caused by coxsackievirus A16, but can also be caused by enterovirus 71; coxsackie A viruses 5, 7, 9, and 10; and coxsackie B viruses 2 and 5. It is usually a mild illness, with or without low-grade fever. The oropharynx is inflamed and contains scattered vesicles on the tongue, buccal mucosa, posterior pharynx, palate, gingiva, and/or lips. These may ulcerate, leaving

4–8?mm shallow lesions with surrounding erythema. Maculopapular, vesicular, and/or pustular lesions may also occur on the hands and fingers, feet, and buttocks and groin; hands are more commonly involved than the feet. Lesions on the hands and feet are usually tender and vesicular and vary in size from 3–7?mm; they are generally more common on the dorsal surfaces but frequently occur on the palms and soles as well. Vesicles resolve in about 1 wk. Buttock lesions do not usually progress to vesiculation. Disseminated vesicular rashes may complicate preexisting eczema.

Hand-foot-and-mouth disease caused by enterovirus 71 is frequently more severe than that due to coxsackievirus A16, with high rates of associated neurologic disease including aseptic meningitis, encephalitis, and paralysis. Recent outbreaks in Malaysia, Japan, and Taiwan have been notable for brainstem encephalomyelitis, neurogenic pulmonary edema, pulmonary hemorrhage, shock, and rapid death, especially in young children.

HERPANGINA.

Herpangina is characterized by a sudden onset of fever, sore throat, dysphagia, and characteristic lesions in the posterior pharynx. Initial temperatures can range from normal to 41°C (106°F); fever tends to be greater in younger patients. Headache and backache may occur in older children, and vomiting and abdominal pain occur in 25%. Oropharyngeal lesions may be present on the anterior tonsillar pillars, soft palate, uvula, tonsils, posterior pharyngeal wall, and, occasionally, the posterior buccal surfaces. Characteristic lesions are discrete 1–2?mm vesicles and ulcers that enlarge over 2–3 days to 3–4?mm and are surrounded by erythematous rings that vary in size up to 10?mm. An average of 5 lesions is usually present (range, 1 to >15). The remainder of the pharynx appears normal or minimally erythematous. Most cases of herpangina are mild and have no complications; however, some are associated with aseptic meningitis or other more severe illness. Fever generally lasts 1–4 days and resolution of symptoms occurs in 3–7 days. A variety of enteroviruses can cause herpangina, although coxsackie A viruses are implicated most often. Some cases of herpangina have been noted during recent outbreaks of enterovirus 71 disease.

RESPIRATORY MANIFESTATIONS.

Respiratory symptoms such as sore throat and coryza frequently accompany enterovirus illnesses. In some cases, respiratory manifestations dominate the clinical presentation. Findings may include upper respiratory symptoms, wheezing, apnea, respiratory distress, pneumonia, otitis media, bronchiolitis, croup, parotitis, and pharyngotonsillitis. In the latter, pharyngeal erythema, occasionally with exudate, may be evident.

Pleurodynia (**Bornholm disease**) is an illness characterized by paroxysmal thoracic pain, due to myositis involving chest and abdominal wall muscles. Etiologic agents are most frequently coxsackieviruses B3 and B5, as well as coxsackieviruses B1 and B2 and echoviruses 1 and 6. Disease may be epidemic or sporadic. In epidemics, children and adults are affected, but most cases occur in persons younger than 30 yr of age. Prodromal symptoms such as malaise, myalgias, and headache are followed by sudden onset of fever and pain. Pain, typically located in the chest or upper abdomen, is spasmodic and can be excruciatingly severe. It is pleuritic and aggravated by coughing, sneezing, deep breathing, or other movement. Spasms last from a few minutes to several hours. During spasms, respirations are usually rapid, shallow, and grunting, suggesting pneumonia or pleural inflammation. A pleural friction rub may be noted during pain episodes, though chest radiographs are most often normal. Pain localized to the abdomen is frequently crampy, suggesting colic in the younger child. A pale, sweaty, shock-like appearance may suggest intestinal obstruction; tenderness and guarding may also suggest appendicitis and peritonitis. Illness usually lasts 3–6 days, but can last up to a couple of weeks. The illness is frequently biphasic. Rarely, patients have several recurrent episodes over a period of a few weeks, with less prominent fever during recurrences. Pleurodynia may occasionally be associated with meningitis, orchitis, myocarditis, or pericarditis.

ACUTE HEMORRHAGIC CONJUNCTIVITIS.

Enterovirus 70 and coxsackievirus A24 are the primary causes of epidemics of acute hemorrhagic conjunctivitis that have occurred in both tropical regions and temperate climates, including the United States. Epidemics are explosive, spread mainly via eye-hand-fomite-eye transmission. Teenagers and adults 20–50 yr of age have the highest attack rates, with young children less often affected. Illness is characterized by sudden onset of severe eye pain associated with photophobia, blurred vision, lacrimation, conjunctival erythema and congestion, and lid edema. Subconjunctival hemorrhages of varying size occur in a fraction of patients, and superficial punctate keratitis is frequently present. Eye discharge is initially serous but becomes mucopurulent with secondary bacterial infection. Preauricular lymphadenopathy may be found. Systemic symptoms including fever are rare, although a picture suggestive of pharyngoconjunctival fever occasionally occurs. Recovery is usually complete within 1–2 weeks. A small number of patients have polyradiculoneuropathy or paralytic disease following enterovirus 70 acute hemorrhagic conjunctivitis.

MYOCARDITIS AND PERICARDITIS.

Enteroviruses are among the most frequent pathogens implicated in myocarditis and pericarditis, accounting for approximately 25–35% of cases with proven cause. Coxsackie B viruses are the most common etiologic types; coxsackie A viruses and echoviruses also may be causative. Myocarditis has been observed in enterovirus 71 outbreaks associated with hand-foot-and-mouth disease and neurologic manifestations. Adolescents and young adults, especially males, are disproportionately affected by enterovirus myocarditis. Myopericarditis may be the dominant feature of illness or it may be part of more disseminated disease, as seen in neonates. Disease ranges from relatively mild to severe and fatal. Upper respiratory symptoms frequently precede cardiac manifestations such as fatigue, dyspnea, chest pain, congestive heart failure, and dysrhythmias. Presentations may mimic myocardial infarction; in other cases, patients present with sudden death. A pericardial friction rub indicates pericardial involvement. Chest radiograph often demonstrates cardiac enlargement. Electrocardiogram frequently reveals ST segment, T wave, and/or rhythm abnormalities, and echocardiogram may confirm cardiac dilatation, reduced contractility, and/or pericardial effusion. Myocardial enzymes may be elevated. The acute mortality of enterovirus myocarditis is 0–4%.

Recovery is complete without residual disability in the majority of survivors. Occasionally, however, chronic cardiomyopathy or constrictive pericarditis may result. The role of possible persistent enterovirus infection in chronic dilated cardiomyopathy is controversial.

GASTROINTESTINAL MANIFESTATIONS.

Gastrointestinal symptoms are frequent with enterovirus infections but are generally not dominant features. Symptoms may include emesis (especially with meningitis), diarrhea that is rarely severe, and abdominal pain. Diarrhea, hematochezia, pneumatosis intestinalis, and necrotizing enterocolitis have been observed in premature infants infected during nursery outbreaks. Enterovirus infection has been implicated as a cause of chronic intestinal inflammation in hypogammaglobulinemic patients.

NEUROLOGIC MANIFESTATIONS.

Enteroviruses are the most common cause of viral meningitis in mumps-immunized populations; they account for over 90% of cases in which a causative agent is identified. Meningitis is particularly common in infants, especially among infants younger than 3 mo of age, and disease frequently occurs as part of community epidemics. Frequently implicated serotypes include coxsackieviruses B2–B5; echoviruses 4, 6, 7, 9, 11, 16, and 30; and enteroviruses 70 and 71. Most cases in infants and young children are mild and lack specific signs and symptoms. Fever is present in 75–100%; other findings may include irritability, malaise, headache, photophobia, nausea, emesis, anorexia, lethargy, rash, cough, rhinorrhea, pharyngitis, diarrhea, and myalgia. Nuchal rigidity is apparent in more than half of children older than 1–2 yr. Some cases are biphasic, with fever and nonspecific symptoms for a few days, followed by absence of symptoms for several days, then return of fever with meningeal signs. Fever usually resolves in 3–5 days, and other symptoms in infants and young children usually resolve within 1 wk. Symptoms tend to be more severe and longer lasting in adults. Cerebrospinal fluid findings include pleocytosis that generally is less than

500?WBC/mm^3 (occasionally as high as 1000–8000?WBC/mm^3) and often consists predominantly of polymorphonuclear cells in the first 48?hr before becoming mostly mononuclear; normal or slightly low glucose, with 10% below 40?mg/dL; and normal or mildly increased protein (generally <100?mg/dL). Cerebrospinal fluid occasionally has normal parameters despite positive viral culture or polymerase chain reaction. Complications of enterovirus meningitis occur in approximately 10% of young children; these include simple and complex seizures, obtundation, increased intracranial pressure, syndrome of inappropriate antidiuretic hormone secretion, and coma. The prognosis for most children with enterovirus meningitis is good. Although earlier studies suggested developmental, language, and cognitive sequelae in young infants, recent larger, prospective, comparative studies have generally not demonstrated long-term adverse outcomes.

Enteroviruses are also responsible for 10–20% of encephalitis with identified cause. Frequently implicated serotypes include echoviruses 3, 4, 6, 9, and 11; coxsackieviruses B2, B4, and B5; coxsackievirus A9, and enterovirus 71. After initial nonspecific symptoms, encephalitis becomes apparent by progression to marked confusion, weakness, lethargy, and/or irritability. Depression is usually generalized, although focal findings such as focal motor seizures, hemichorea, acute cerebellar ataxia, focal neurologic deficits, and/or focal imaging abnormalities may occasionally occur. Encephalitis includes a spectrum of disease from altered mental status to coma to decerebrate status; long-term neurologic sequelae may follow more severe disease.

Neurologic disorders have been prominent in recent epidemics of enterovirus 71 disease. The majority of affected children had hand-foot-and-mouth disease, some had herpangina, and others had no mucocutaneous manifestations. Neurologic syndromes observed included meningitis, meningoencephalomyelitis, poliomyelitis-like paralytic disease, Guillain-Barré syndrome, transverse myelitis, cerebellar ataxia, opsoclonus-myoclonus syndrome, benign intracranial hypertension, and brainstem encephalitis (rhombencephalitis involving the midbrain, pons, and medulla). The latter is characterized by myoclonus, vomiting, ataxia, nystagmus, tremor, and cranial nerve abnormalities. Although findings were mild and reversible in some, in others rapid progression to neurogenic pulmonary edema and hemorrhage, shock, and coma developed. High mortality rates have been reported, especially in children younger than 5 yr of age. Neurologic deficits have been observed among surviving children.

Patients with antibody deficiencies are at risk for chronic meningoencephalitis characterized by persistent cerebrospinal fluid (CSF) abnormalities, viral detection by culture or polymerase chain reaction for years, and recurrent encephalitis and/or progressive neurologic deterioration. Clinical findings include altered mental status, seizures, motor weakness, and increased intracranial pressure. Although the disease may wax and wane, deficits generally become progressive, and ultimately may be fatal. A dermatomyositis-like syndrome and hepatitis may supervene in advanced stages. Fortunately, chronic enterovirus meningoencephalitis has become less common in hypogammaglobulinemic patients receiving routine antibody replacement with intravenous immunoglobulin.

Nonpolio enteroviruses, especially enteroviruses 70 and 71, coxsackievirus A7, and coxsackie B viruses, can cause poliomyelitis- like paralytic disease with acute motor weakness due to anterior horn cell involvement. Disease tends to be milder than that caused by poliovirus, with less bulbar involvement and less persistent weakness.

Other neurologic syndromes observed with enterovirus infections include cerebellar ataxia, transverse myelitis, Guillain-Barré syndrome, and peripheral neuritis.

MYOSITIS AND ARTHRITIS.

Although myalgia is a common complaint accompanying enterovirus illness, direct evidence of muscle involvement has only occasionally been reported. Several enterovirus types have been associated with focal myositis and polymyositis. A dermatomyositis-like syndrome can be seen in enterovirus-infected hypogammaglobulinemic patients. Enteroviruses have rarely been demonstrated to

cause arthritis.

PANCREATITIS AND ORCHITIS.

A variety of coxsackie B virus and echovirus serotypes have been reported to cause pancreatitis. Coxsackie B viruses are second only to mumps as causative agents of orchitis. The illness is frequently biphasic; fever and pleurodynia or meningitis are followed by apparent recovery and then, in about 2 weeks, by orchitis, often with epididymitis.

NEONATAL INFECTIONS.

Enterovirus infections in neonates are relatively common, with an incidence of clinical disease comparable to or greater than that of symptomatic neonatal infections due to herpes simplex virus, cytomegalovirus, and group B *Streptococcus*. Infection frequently is with coxsackieviruses B2–B5 and echoviruses 6, 9, 11, and 19, although many enterovirus serotypes have been implicated. Enteroviruses may be acquired vertically before, during, or after delivery; they also may be acquired horizontally from other infected family members or by transmission in hospital nurseries (sporadic or epidemic). Infection in utero may be associated with placentitis, fetal demise, neonatal illness, and, possibly, congenital anomalies. Neonatal infection is associated with a range of clinical manifestations, from asymptomatic (the majority) to benign febrile illness to severe multisystem disease. Most affected newborns are full-term and previously well; maternal history often reveals a recent viral illness, including fever and, frequently, abdominal pain. Symptoms in the neonate may occur throughout the newborn period, with some beginning as early as day 1 of life; severe disease generally has an onset within the first 2 wk of life. Frequent findings include fever or hypothermia, irritability, lethargy, anorexia, rash (usually maculopapular, occasionally petechial or papulovesicular), jaundice, respiratory symptoms, apnea, hepatomegaly, abdominal distention, emesis, diarrhea, and decreased perfusion. Most symptomatic neonates have benign courses, with resolution of fever in an average of 3 days and of other symptoms in about 1 wk. Occasionally, a biphasic course may occur. A minority has severe disease that may be dominated by any combination of sepsis, meningoencephalitis, myocarditis, hepatitis, coagulopathy, and pneumonitis. Meningoencephalitis may be indicated by focal or complex seizures, bulging fontanelle, nuchal rigidity, or reduced level of consciousness. Myocarditis, most often associated with coxsackie B virus infection, may be suggested by tachycardia, dyspnea, cyanosis, and cardiomegaly. Hepatitis is more associated with echovirus infection, although it may occur with coxsackie B viruses; pneumonitis is also more frequently seen with echovirus infection. Laboratory evaluation may reveal leukocytosis, thrombocytopenia, pleocytosis, elevated transaminases and bilirubin, coagulopathy, pulmonary infiltrates, and electrocardiographic changes. Complications include CNS necrosis and generalized or focal neurologic compromise; arrhythmias, congestive heart failure, myocardial infarction, and pericarditis; hepatic necrosis and failure; intracranial or other bleeding; adrenal necrosis and hemorrhage; and rapidly progressive pneumonitis. Myositis, necrotizing enterocolitis, inappropriate antidiuretic hormone secretion, hemophagocytic syndrome, and sudden death are rare events. Mortality in those with severe disease is significant and is most often associated with hepatitis and associated bleeding complications, myocarditis, or pneumonitis. The majority of surviving infants have gradual resolution of hepatic and cardiac dysfunction, although chronic calcific myocarditis can occur. CNS infection, especially if clinical signs of encephalitis are present, may be associated with morbidity such as speech and language impairment; cognitive deficits; spasticity, hypotonicity, or weakness; seizure disorders; microcephaly or hydrocephaly; and ocular abnormalities. However,

most survivors appear not to have long-term sequelae. Risk factors for severe disease include illness onset in the first few days of life, maternal illness just prior to or at delivery, prematurity, male sex, infection by echovirus 11 or a coxsackie B virus, positive serum viral culture, absence of neutralizing antibody to the infecting virus, and evidence of severe hepatitis and/or multisystem disease.

BONE MARROW TRANSPLANT RECIPIENTS.

In recent years, a variety of severe and/or prolonged enterovirus infections have been reported in bone marrow and stem cell transplant recipients. Cases include progressive pneumonia, severe diarrhea, pericarditis and heart failure, and disseminated disease. High fatality rates have been reported.

Diagnosis.

Enterovirus infection can often be suspected on clinical grounds, especially when relatively specific clinical findings such as hand-foot-and-mouth disease or herpangina lesions are present. Additional clues include consistent seasonality, known community outbreak, and exposure to enterovirus-compatible disease. In the neonate, history of maternal fever, malaise, and/ or abdominal pain near delivery during enterovirus season is suggestive.

Viral culture using a combination of cell lines that support the growth of enteroviruses is the gold standard method for confirmation of infection. Sensitivity of culture is in the range of 50–75%. Sensitivity is increased by culturing multiple sites. For example, in children with meningitis, culture yield is enhanced by culturing CSF plus additional sites such as throat and rectum. In neonates, significant yields (30–70%) have been observed when blood, urine, and CSF are cultured in addition to mucosal swabs. A major limitation of culture is the inability of most coxsackie A viruses to grow in culture. Coxsackie A viruses are more readily identified by their pathologic effects in suckling mice, a technique generally available only in research laboratories. Culture yield may also be limited by the presence of neutralizing antibody in patient specimens, improper specimen handling, or insensitivity of the cell lines used. Additionally, culture is relatively slow, with 3–8 days usually required to detect growth. Antigen detection has been coupled with culture to shorten the time required for viral detection, but sensitivity has been a limiting factor. In general, cultivation of an enterovirus from any site can be considered evidence of recent infection; however, isolation from the rectum or stool can also reflect shedding from a more remote infection. Similarly, recovery from a mucosal site may suggest an association with an illness, whereas recovery from a normally sterile site such as CSF, blood, or tissue is more conclusive evidence of causation. Serotype identification can be performed in reference laboratories by testing with neutralizing antisera. This is generally only required for investigation of an outbreak or an

unusual disease manifestation or to distinguish nonpolio enteroviruses from polioviruses (vaccine type or wild type).

Direct testing of patient specimens for enterovirus antigen or nucleic acid has been pursued to overcome the limitations of culture, that is, imperfect sensitivity and delayed results. Antigen detection, such as by enzyme-linked immunosorbent assay, has had some success, but sensitivity is limited by the lack of surface antigens shared by the majority of enteroviruses. Greater success has been achieved by applying reverse transcription polymerase chain reaction (PCR) to detection of highly conserved areas of the 5' non-coding region of the enterovirus genome. This approach, which detects the majority of enteroviruses (but frequently not echoviruses 22 and 23), has been applied to a variety of specimens, including CSF, serum, urine, and conjunctival, nasopharyngeal, throat, and rectal specimens. Sensitivity and specificity are high, and testing can be accomplished in periods as short as five hours. PCR testing of CSF from children with acute aseptic meningitis and from hypogammaglobulinemic patients with chronic enterovirus meningoencephalitis are frequently positive despite negative cultures. In ill neonates, PCR testing of serum and urine specimens is associated with higher yields than culture of these fluids. Routine application of PCR to testing of CSF from infants and young children with meningitis has been demonstrated to decrease diagnostic testing, duration of hospital stay, antibiotic use, and overall costs.

Enterovirus infections can be detected serologically, either by demonstration of a rise in neutralizing, complement fixation, or other type-specific antibody or by detection of serotype-specific IgM antibody. However, serologic testing requires presumptive knowledge of the infecting serotype, either by isolation of a virus from the patient or a contact or by association with a community epidemic of a known serotype. Sensitivity may also be limited. In general, except for epidemiologic studies, serology is less useful than is viral culture or nucleic acid detection.

Enterovirus infection may be diagnosed by detection of virus in tissue specimens, such as biopsies of myocardium, liver, or brain. Detection methods include culture, nucleic acid detection by PCR or in situ hybridization, and antigen detection by immunofluorescence.

Differential Diagnosis.

The differential diagnosis of enterovirus infections varies with the clinical presentation (Table 229–1).

Treatment.

Newborns, infants, and children presenting with nonspecific febrile illnesses or meningitis due to enterovirus infections frequently require diagnostic evaluations for bacterial and herpes simplex virus infection. Hospitalization is often indicated for presumptive treatment of these causes until tests rule out these diagnoses. Neonates with severe disease, infants, and children with myocarditis and patients with concerning neurologic diseases may require intensive supportive care, including cardiorespiratory support and blood product administration.

Immune globulin has been used as a potential therapy for enterovirus infections for several reasons. The humoral immune response to enteroviruses is a key defense against infection, and

TABLE 229-1 -- **Differential Diagnosis of Enterovirus Infections**

Clinical Manifestation	Bacterial Pathogens	Viral Pathogens
Nonspecific febrile illness	*Streptococcus pneumoniae, Haemophilus influenzae* type b, *Neisseria meningitidis*	Influenza viruses, human herpesviruses 6 and 7
Exanthems/enanthems	Group A streptococcus, *Staphylococcus aureus, Neisseria meningitidis*	Herpes simplex virus, adenoviruses, varicella-zoster virus, Epstein-Barr virus, measles virus, rubella virus, human herpesviruses 6 and 7
Respiratory illness/conjunctivitis	*Streptococcus pneumoniae, Haemophilus influenzae* type b, *Neisseria meningitidis, Mycoplasma pneumoniae, Chlamydia pneumoniae*	Adenoviruses, influenza viruses, respiratory syncytial virus, parainfluenza viruses, rhinovirus
Myocarditis/pericarditis	*Staphylococcus aureus, Haemophilus influenzae* type b, *Mycoplasma pneumoniae*	Adenoviruses, influenza virus, other viruses
Meningitis/encephalitis	*Streptococcus pneumoniae, Haemophilus influenzae* type b, *Neisseria meningitidis, Mycobacterium tuberculosis, Borrelia burgdorferi, Mycoplasma pneumoniae, Bartonella henselae, Listeria monocytogenes*	Herpes simplex virus, influenza viruses, adenovirus, Epstein-Barr virus, mumps virus, lymphocytic choriomeningitis virus, arboviruses
Neonatal infections	Group B streptococcus, gram-negative enteric bacilli, *Listeria monocytogenes, Enterococcus*	Herpes simplex virus, adenoviruses, cytomegalovirus, rubella virus

lack of neutralizing antibody is a risk factor for symptomatic infection. Immune globulin products contain neutralizing antibodies to many of the commonly circulating serotypes, although titers vary with serotype and among products. Routine use of maintenance intravenous immune globulin for hypogammaglobulinemic patients has been associated with a decrease in chronic enterovirus disease. Therefore, anecdotal, uncontrolled use of intravenous immune globulin to treat newborns with severe disease has been reported. The one reported randomized, controlled trial was too small to demonstrate significant clinical benefits, although neonates who received immune globulin containing a high neutralizing titer to their own isolates had

shorter periods of viremia and viruria. Infusion of maternal convalescent plasma has also been anecdotally reported. Intravenous and intraventricular immune globulin have been used to treat hypogammaglobulinemic patients with chronic enterovirus meningoencephalitis, with variable success. A retrospective study suggested treatment of myocarditis with immune globulin was associated with improved outcome; virologic diagnoses were not made in this study. Evaluation of corticosteroids and other immunosuppressive therapy for myocarditis has been inconclusive.

Specific antiviral therapy for enterovirus infections is being developed. Agents that act at several key steps in the enterovirus life cycle, including attachment, uncoating, protease activity, and replication, are being evaluated. The investigational agent that has advanced furthest, pleconaril, fits within a pocket beneath the floor of a canyon at the junctions of VP1 and VP3 on the viral capsid and inhibits viral attachment and uncoating. Its use was associated with modest acceleration of symptom resolution in some clinical trials involving children and adults with enterovirus meningitis and slightly faster clinical resolution of upper respiratory tract infections caused by picornaviruses (enteroviruses or rhinoviruses). Other conditions in which this generally well tolerated, oral medication is being evaluated include severe neonatal enterovirus infection, myocarditis, encephalitis, paralytic disease, and infections in immunodeficient patients. Uncontrolled experience suggests possible treatment benefits in these high-risk conditions.

Complications.

Complications of enterovirus infections are primarily those associated with the clinical manifestations of myocarditis and encephalitis, and also severe neonatal infections following peripartum transmission.

Prognosis.

The prognosis in the vast majority of enterovirus infections is excellent. Morbidity and mortality are primarily related to myocarditis, neurologic syndromes, severe neonatal disease, and infections in immune compromised hosts. Specific comments are included with the descriptions of these clinical manifestations.

Prevention.

Vaccines for enteroviruses (other than polioviruses) are not available. The first line of defense against transmission of enteroviruses is basic hygiene such as handwashing to prevent fecal-oral and respiratory spread within families, preschools, and schools. Infection control techniques such as cohorting have proven effective in limiting nursery outbreaks. Prophylactic administration of intramuscular or intravenous immunoglobulin or convalescent plasma has been used in some nursery epidemics to prevent infection or ameliorate symptomatic disease. Simultaneous infection control interventions make it difficult to determine the efficacy of these approaches.

Pregnant women near term should avoid contact with individuals ill with probable enterovirus infections. If a pregnant woman develops an illness considered likely to be caused by an enterovirus, it is advisable not to proceed with emergent delivery unless there is concern for fetal compromise or that obstetric emergencies cannot be excluded. Rather, it may be advantageous to extend pregnancy, allowing the fetus time to passively acquire protective antibodies. A strategy of prophylactically administering immune globulin to neonates born to mothers with enterovirus infections near delivery is untested.

Maintenance antibody replacement with intravenous immune globulin for patients with hypogammaglobulinemia has reduced the incidence of chronic enterovirus meningoencephalitis among these patients.

Chapter 230 - Parvovirus B19

William C. Koch

The frequency of B19 infection in the general pediatric population was not fully appreciated until 1983, when Anderson and colleagues identified B19 as the cause of **erythema infectiosum** or **fifth disease**, which is a classic, well-recognized childhood exanthem.

Etiology.

Parvovirus B19 (B19) is a member of the genus *Erythrovirus* in the family Parvoviridae. Parvoviruses are small DNA viruses that infect a variety of animal species. As a group, the parvoviruses include a number of important animal pathogens including canine parvovirus and feline panleukopenia virus. Discovered in 1975, B19 is the only parvovirus that is pathogenic in humans. It does not infect other animals, and animal parvoviruses do not infect humans.

B19 is composed of an icosahedral protein capsid without an envelope that contains single-stranded DNA approximately 5.5?kb in length. It is relatively heat- and solvent-resistant. It is antigenically distinct from other mammalian parvoviruses, and there is only one known serotype. Parvoviruses replicate in mitotically-active cells. Because of their limited genome, they require host cell factors present in late S phase to replicate. B19 can be propagated only in erythropoietin-stimulated erythropoietic cells derived from human bone marrow, umbilical cord blood, or primary fetal liver culture.

Epidemiology.

Infections with parvovirus B19 are common and worldwide. Clinically apparent infections, such as rash illness and transient aplastic crisis, are most prevalent in school-aged children, with 70% of cases occurring between 5 and 15 yr of age. Seasonal peaks occur in the late winter and spring; sporadic infections occur throughout the year. Seroprevalence increases with age; 40–60% of adults have evidence of prior infection.

Transmission of B19 is by the respiratory route, presumably via large droplet spread from nasopharyngeal viral shedding. The transmission rate in households ranges from 15 to 30% in

susceptible contacts; mothers are more commonly infected than fathers. In outbreaks of erythema infectiosum in elementary schools, the secondary attack rates range from 10–60%. Nosocomial outbreaks are described, with secondary attack rates of 30% in susceptible health care workers.

Although respiratory spread is the primary mode of transmission, B19 is transmissible in blood and blood products, which has been documented among children with hemophilia receiving pooled donor clotting factor. Given the resistance of the virus to solvents, fomite transmission could be important in childcare and other group settings, but this mode of transmission has not been documented.

Pathogenesis.

The primary target of B19 infection is the erythroid cell line, specifically erythroid precursors near the pronormoblast stage. Viral infection produces lysis of these cells, leading to a progressive depletion and a transient arrest of erythropoiesis. The virus has no apparent effect on the myeloid cell line. The tropism for erythroid cells is related to the erythrocyte P blood group antigen, which serves as a cellular receptor for the virus. Endothelial cells, placenta, and fetal myocardial cells also possess this antigen. Thrombocytopenia and neutropenia are often observed clinically, but their pathogenesis is unexplained.

Experimental infection of normal volunteers revealed a biphasic illness. From 7 to 11 days after inoculation, the subjects had viremia and nasopharyngeal viral shedding and experienced fever, malaise, and rhinorrhea. Their reticulocyte counts dropped to undetectable levels but resulted only in a mild, clinically insignificant fall in serum hemoglobin. Symptoms resolved and hemoglobin returned to normal with the appearance of specific antibodies. Several subjects experienced a rash associated with arthralgia 17–18 days after inoculation. Some manifestations of B19 infection, such as transient aplastic crisis, appear to be a direct result of viral infection, whereas others, including the exanthem and arthritis, appear to be postinfectious phenomena related to the immune response. Skin biopsy results from patients with erythema infectiosum are compatible with an immune process, showing edema in the epidermis and a perivascular mononuclear infiltrate.

Individuals with chronic hemolytic anemia and increased red cell turnover are very susceptible to perturbations in erythropoiesis. Infection with B19 leads to a transient arrest in red cell production and a precipitous fall in serum hemoglobin, often requiring transfusion. The reticulocyte count falls to near zero, reflecting the lysis of infected erythroid precursors. Humoral immunity is crucial in controlling infection. Specific immunoglobulin M (IgM) appears within 1–2 days followed by anti-B19 IgG, leading to control of the infection, restoration of reticulocytosis, and a rise in serum hemoglobin.

Individuals with impaired humoral immunity are at increased risk for more serious or persistent infection with B19, which usually manifests as chronic red cell aplasia, but

neutropenia, thrombocytopenia, and marrow failure are also described. Children on chemotherapy for leukemia, those with congenital immunodeficiency states, transplant patients, and those with AIDS are at risk for chronic B19 infections.

Infections in the fetus and neonate are somewhat analogous to infections in the immunocompromised host. B19 is associated with nonimmune fetal hydrops and stillbirth in women experiencing a primary infection but does not appear to be teratogenic. Like most mammalian parvoviruses, B19 can cross the placenta and cause fetal infection during primary maternal infection. Parvovirus cytopathic effects are seen primarily in erythroblasts of the bone marrow and sites of extramedullary hematopoiesis in the liver and spleen. Fetal infection can presumably occur as early as 6 wk of gestation, when erythroblasts are first found in the fetal liver; after the 4th gestational month hematopoiesis switches to the bone marrow. In some cases, fetal infection leads to a profound fetal anemia and subsequent high-output cardiac failure (Chapter 92). Fetal hydrops ensues, often associated with fetal mortality. There may also be a direct effect of the virus on myocardial tissue that contributes to the cardiac failure. However, most infections during pregnancy result in normal deliveries at term. Some of these asymptomatic infants have been reported to have chronic postnatal infection with B19 that is of unknown significance.

Clinical Manifestations.

Many infections are clinically inapparent. Children characteristically develop erythema infectiosum. Adults, especially women, frequently develop acute arthropathy with or without the rash of erythema infectiosum.

ERYTHEMA INFECTIOSUM (FIFTH DISEASE).

The most common manifestation of parvovirus B19 is erythema infectiosum, also known as fifth disease, which is a benign, self-limited exanthematous illness of childhood. It was the fifth in a classification scheme of childhood exanthems. The preceding four exanthems were measles, scarlet fever, rubella and Filatov-Dukes disease (an atypical scarlet fever), with roseola infantum as the “sixth disease.”

The incubation period for erythema infectiosum ranges from 4 to 28 days (average, 16–17 days). The prodromal phase is mild and consists of low-grade fever, headache, and symptoms of mild upper respiratory tract infection. The hallmark of erythema infectiosum is the characteristic rash, which occurs in three stages that are not always distinguishable. The initial stage is an erythematous facial flushing, often described as a “slapped-cheek” appearance. The rash spreads rapidly or concurrently to the trunk and proximal extremities as a diffuse macular erythema in the second stage. Central clearing of macular lesions occurs promptly, giving the rash a lacy, reticulated appearance. Palms and soles are spared, and the rash tends to be more prominent on extensor surfaces. Affected children are afebrile and not ill-appearing. Older children and adults often complain of mild pruritus. The rash resolves spontaneously without desquamation but tends to wax and wane over 1–3 wk. It can recur with exposure to sunlight, heat, exercise, and stress. Lymphadenopathy and atypical papular, purpuric, vesicular rashes are also described.

ARTHROPATHY.

Arthritis and arthralgia occur as a complication of fifth disease or as the only clinical manifestation of B19 infection. Joint symptoms are much more common in adults and older adolescents. Females are affected more frequently than males. In one outbreak of fifth disease, 60% of adults and 80% of adult women reported joint symptoms. Joint symptoms range from diffuse arthralgias with morning stiffness to frank arthritis. The joints most often affected are the hands, wrists, knees, and ankles, but practically all have been reported. The joint symptoms are self-limited and, in the majority of patients, resolve within 2–4 wk. Some patients may have a prolonged course of many months, suggesting rheumatoid arthritis. Transient rheumatoid factor positivity is reported in some of these patients but with no joint destruction.

TRANSIENT APLASTIC CRISIS.

The incubation period for transient aplastic crisis is shorter than for erythema infectiosum because it occurs coincident with the viremia. The transient arrest of erythropoiesis and absolute reticulocytopenia induced by B19 infection leads to a sudden fall in serum hemoglobin in individuals with chronic hemolytic conditions. B19-induced aplastic crises occur in patients with all types of chronic hemolysis, including sickle cell disease, thalassemia, hereditary spherocytosis, and pyruvate kinase deficiency. In contrast to children with erythema infectiosum, these patients are ill with fever, malaise, and lethargy and have signs and symptoms of profound anemia, such as pallor, tachycardia, and tachypnea. Rash is rarely present. Children with sickle cell hemoglobinopathies may also have a concurrent vaso-occlusive pain crisis.

IMMUNOCOMPROMISED PERSONS.

Patients with impaired humoral immunity are at risk for chronic infections with parvovirus B19. Chronic anemia is the most common manifestation,

---

sometimes accompanied by neutropenia, thrombocytopenia, or complete marrow suppression. Chronic infections are seen in children with cancer receiving cytotoxic chemotherapy, children with congenital immunodeficiencies, patients on immunosuppressive therapy for transplants, children (and adults) with AIDS, and patients with functional defects in IgG production who are unable to generate neutralizing antibodies.

FETAL INFECTION.

Primary maternal infection is associated with nonimmune fetal hydrops and intrauterine fetal demise; the risk of fetal loss after infection is estimated at <5%. The mechanism of fetal disease appears to be a viral-induced red cell aplasia at a time when the fetal erythroid fraction is rapidly expanding. This can lead to profound

anemia, high-output cardiac failure, and hydrops. Viral DNA has been detected in infected abortuses. The second trimester seems to be the most sensitive period, but fetal losses are reported at every stage of gestation. Most infants infected in utero are born normally at term, even some with ultrasonographic evidence of hydrops. Some of these infants may acquire a chronic or persistent postnatal infection with B19, but its significance is unknown. Congenital anemia associated with intrauterine B19 infection has been reported in a few cases, sometimes following intrauterine hydrops. This process may mimic other forms of congenital hypoplastic anemia (i.e., Diamond-Blackfan syndrome). Fetal infection with B19 has not been associated with other birth defects. B19 is only one of many causes of hydrops fetalis (Chapter 92).

MYOCARDITIS.

B19 infection has been associated with cases of myocarditis in fetuses, infants, children and a few adults. Diagnosis has often been based on serology suggestive of a concurrent B19 infection but in many cases B19 DNA has been demonstrated in cardiac tissue. This is plausible because fetal myocardial cells are known to express the receptor for the virus (P antigen). In the few cases where histology is reported, a predominantly lymphocytic infiltrate is described. Outcomes have varied from complete recovery to chronic cardiomyopathy to fatal cardiac arrest. Although B19-associated myocarditis appears to be a rare occurrence, there appears to be enough evidence to consider B19 as a potential cause of lymphocytic myocarditis, especially in infants.

OTHER CUTANEOUS MANIFESTATIONS.

A variety of atypical skin eruptions have been reported in association with B19 infection. Most of these are petechial or purpuric in nature, often with evidence of vasculitis on those on which biopsies have been performed. Among these, the **papular-purpuric “gloves and socks” syndrome (PPGSS)** appears well established in the dermatologic literature as distinctly associated with B19 infection. PPGSS is characterized by fever, pruritus, and painful edema and erythema localized to the distal extremities in a distinct glove and sock distribution, followed by acral petechiae and oral lesions. The syndrome is self-limited and resolves within a few weeks. Initially described in young adults, a number of reports in children have since been published. In those linked to B19 infection, the eruption is accompanied by serologic evidence of acute infection.

Diagnosis.

The diagnosis of erythema infectiosum is usually based on clinical presentation of the typical rash. Similarly, the diagnosis of a typical transient aplastic crisis in a child with sickle cell disease rarely requires virologic confirmation.

Serologic tests for the diagnosis of B19 infection are available. B19-specific IgM develops rapidly after infection and persists for 6–8 wk. Anti-B19 IgG serves as a marker of past infection or immunity. Determination of anti-B19 IgM is the best marker of recent/acute infection on a single serum sample; seroconversion of anti-B19 IgG antibodies in paired sera can also be used to confirm recent infection. Serologic diagnosis is unreliable in immunocompromised patients; diagnosis in these patients requires methods to detect viral DNA.

The virus cannot be isolated by culture. Methods to detect viral particles or viral DNA such as polymerase chain reaction (PCR) or nucleic acid hybridization are necessary to establish the diagnosis. Prenatal diagnosis of B19-induced fetal hydrops can be accomplished by detection of viral DNA in fetal blood by these methods or visualization of viral particles by immune electron microscopy.

DIFFERENTIAL DIAGNOSIS.

The rash of erythema infectiosum must be differentiated from that of rubella, measles, enteroviral infections, and drug reactions. Rash and arthritis in older children should prompt consideration of juvenile rheumatoid arthritis, systemic lupus erythematosus, and other connective tissue disorders.

Treatment.

There is no specific antiviral therapy. Commercial lots of intravenous immunoglobulin (IVIG) have been used with some success to treat B19-related episodes of anemia and bone marrow failure in immunocompromised children. Specific antibody may facilitate clearance of the virus; it is not always necessary, however, because cessation of cytotoxic chemotherapy will often suffice. In patients whose immune status is not likely to improve, such as patients with AIDS, administration of IVIG may give only a temporary remission, and periodic re-infusions may be required.

B19-infected fetuses with anemia and hydrops have been managed successfully with intrauterine transfusions, but this has significant attendant risks. Once fetal hydrops is diagnosed, regardless of the suspected cause, the mother should be referred to a fetal therapy center for further evaluation because of the high risk for serious complications (Chapter 92).

Complications.

Erythema infectiosum is often accompanied by arthralgias or arthritis in adolescents and adults, which may persist after resolution of the rash. B19 may cause thrombocytopenic purpura and, rarely, aseptic meningitis in normal individuals after erythema infectiosum. B19 is also a cause of virus-associated hemophagocytic syndrome, usually in immunocompromised patients.

Prevention.

Children with erythema infectiosum are not likely to be infectious at presentation because the rash and arthropathy represent immune-mediated, postinfectious phenomena. Isolation and exclusion from school or childcare are unnecessary and ineffective after diagnosis.

Children with B19-induced red cell aplasia (transient aplastic crisis) are infectious when they present and demonstrate a more intense viremia. Most of these children require transfusions and supportive care until their hematologic status stabilizes. They should be isolated in the hospital to prevent spread to susceptible patients and

staff. Isolation should continue for at least 1 wk and until after resolution of fever. Pregnant caregivers should not be assigned to these patients. Exclusion of pregnant women from workplaces where children with erythema infectiosum may be present (e.g., schools) is not recommended as a general policy because it is unlikely to reduce their risk. There are no data to support the use of IVIG for postexposure prophylaxis in pregnant caregivers or immunocompromised children. No vaccine is available.

Chapter 231 - Herpes Simplex Virus

Steve Kohl

Herpes simplex virus (HSV) infection is common among humans and has a variety of clinical manifestations involving the skin, mucous membranes, eye, central nervous system (CNS), and genital tract. It also causes generalized systemic disease. Disease manifestations are in large part determined by the immune competence of the host. Two strains of the virus are identified: HSV-1 commonly infects skin and mucous membranes above the waist, and HSV-2 commonly infects the genitals and the neonate.

Three types of infection are recognized: primary infection; first infection, nonprimary; and recurrent. **Primary infection** represents infection in HSV-seronegative persons, and is the susceptible host's first experience with the virus, which in most instances is subclinical infection or limited to local superficial lesions accompanied by varying degrees of systemic reaction. In newborns, immunocompromised persons, and severely malnourished infants, a serious systemic infection, often without superficial lesions, may occur. Circulating antibodies and a cell-mediated response develop following infection.

First infection, nonprimary, is infection in a person with immunity to one type of HSV (e.g., type 1) but infection by a second type (e.g., type 2). These infections are usually less severe than primary infection. In pregnant women near delivery, first infection nonprimary disease can lead to severe infection in the newborn owing to the absence of type-specific antibody.

Recurrent infection represents reactivation of a latent infection in an immune host with circulating antibodies. Reactivation follows such nonspecific stimuli as changes in the external milieu (e.g., cold, ultraviolet light) or in the internal milieu (e.g., menstruation, fever, or emotional stress). The lesions tend to be localized and, generally, are not associated with systemic reactions. In immunocompromised persons, especially with T- or natural killer lymphocyte defects, lesions may be progressive if untreated. Viral reactivation may take place in the absence of clinical recurrence, leading to asymptomatic viral shedding.

Etiology.

HSV is a double-stranded DNA-containing enveloped virus. The icosahedral protein

core is surrounded by a lipid envelope in which are embedded a number of viral glycoproteins (e.g., glycoproteins B, C, D, E, G, I, J, K, L) responsible for viral–target cell interaction and infection. These glycoproteins are also key targets for the host humoral and cellular immune response. HSV grows rapidly in human and nonhuman cell lines and produces characteristic cytopathic changes. HSV-1 and HSV-2 are about 50% homologous by nucleic acid analysis and share immunologic cross reactivity but may be differentiated by DNA analysis (endonuclease restriction analysis) and commercially by reactivity with type-specific monoclonal antibodies in a variety of fluorescent and enzyme-linked immunosorbent assays (ELISA). Several enzymes important for viral DNA synthesis, such as thymidine kinase and DNA polymerase, are targets for antiviral agents.

Epidemiology.

The virus develops an extremely compatible relationship with its host. In about 85% of instances the infection is subclinical. Even when clinical manifestations are present, the host is only rarely seriously disabled. Occasionally, the primary or recurrent infection may lead to institutional or family outbreaks of stomatitis, which has been reported in orphanages and daycare center settings. HSV may also be transmitted by infection of digits (**herpetic whitlow**), during contact sports such as rugby or wrestling (**herpes gladiatorum**), and rarely in the hospital setting. The incubation period is 2–12 days (average, 6 days). The spread of infection appears to be determined by two factors: close body contact and trauma such as teething or a break in the skin.

The higher incidence of HSV antibodies in lower socioeconomic groups correlates with crowded living conditions. The epidemiology differs for the two types of HSV. In low-income socioeconomic groups, most infants have transplacental antibody for about the first 6 mo of life. There is a sharp rise in seroprevalence from 1 to 4 yr of age corresponding to antibodies to HSV-1, a much slower rate of acquisition to 14 yr of age, and then a second sharp rise in antibodies, principally to HSV-2. HSV-1 antibodies are found in 30% of university students. Recent serologic studies have indicated a rise in the prevalence of HSV-2 antibody in the United States to 21.7%. Among adults, HSV-2 antibodies are present in up to 60% of adults in lower socioeconomic groups, 10–30% of adults in higher socioeconomic groups, and 3% in nuns. Approximately 10% of HSV-2 seronegative persons with HSV-2-seropositive sexual partners will become infected each year. Approximately 2% of pregnant women in the United States acquire a new HSV infection during the 9 months of pregnancy.

Once infected, the majority of individuals continue to carry the virus in a latent state in neuronal ganglia and maintain an almost constant level of circulating antibodies. The initial level of antibodies reached after a primary infection may fall and several subclinical recurrences may occur before a stable antibody level is established. Carriers may distribute the virus without having any manifest lesion. HSV can be isolated from the oropharynx of 1–2% of asymptomatic adults.

Pathogenesis.

The pathologic changes vary with the tissue infected. In general, a specific lesion is characterized by the presence of intranuclear inclusion bodies, which are homogeneous masses lying in the middle of a severely disorganized nucleus in which the basic chromatin has marginated to the nuclear membrane. Around the specific lesion there is always evidence of an acute inflammatory reaction. In the skin and mucous membranes the typical lesion is a unilocular vesicle. In the skin, the vesicle is tense. Ballooned epithelial cells containing intranuclear inclusions can best be seen at the margins of the vesicle. The vesicular fluid contains infected epithelial cells, including multinucleated giant cells and leukocytes. In the corium there is no necrosis, but capillaries are dilated and there is infiltration with mononuclear and polymorphonuclear cells. In the mucous membrane, because of maceration, there is early leakage of the vesicular fluid, resulting in a collapsed vesicle, mainly filled with fibrin. The edematous roof cells form a gray membrane over the ulcerated lesion.

In otherwise healthy persons, the lesions are confined to the skin and mucous membranes; viremia has rarely been described. Bloodstream spread of the virus with resultant widely disseminated disease occurs mainly in the newborn, in severely malnourished children, in persons with skin diseases such as eczema, and in those with defects in cell-mediated immunity. In these patients the virus spreads hematogenously from the portal of entry to susceptible organs. Virus increases within these organs, and secondary viremia occurs with evidence of extensive cell destruction. It is probable, however, that most cases of HSV-1 encephalitis other than in the newborn are caused by

neurogenic transmission of the virus to the brain. Healing begins with clearing of the viremia and a decrease in the production of virus within the cells. This is accomplished by the coordinated effect of antibody and cell-mediated immunity including T and natural killer cells, as well as a variety of cytokines and complement.

Clinical Manifestations.

HSV characteristically produces vesicular skin lesions. Only rarely is there a viremic distribution that results in widespread systemic disease or neurogenic transmission that leads to meningoencephalitis. Although the occurrence of primary and recurrent lesions is an accepted characteristic of herpetic infection, their distinction clinically is often not possible without knowledge of the presence or absence of homologous type-specific serum antibodies in the patient.

SKIN AND MUCOUS MEMBRANES.

Skin lesions consist of aggregates of thin-walled vesicles on an erythematous base. These rupture, scab, and heal within 7–10 days without leaving a scar except after repeated attacks or secondary bacterial infections; temporary depigmentation may occur in darkly pigmented individuals. The lesions may be preceded by mild irritation or burning at the local site or by severe neuralgic pain in the region. The vesicles may become secondarily infected, introducing impetigo into the differential diagnosis. The lesions tend to recur at the same site, particularly at mucocutaneous junctions, but may occur anywhere.

Primary infection, especially in immunocompromised persons, may, uncommonly, result in a generalized vesicular eruption in which the lesions are small and may continue to appear over a period of 2–3 wk. If the systemic manifestations are mild, the infection must be differentiated from varicella.

Traumatic lesions of the skin or burns can be infected by HSV. Primary lesions can also occur on apparently unbroken skin, as, for example, on the chin of a drooling infant with herpetic stomatitis, in whom scattered isolated vesicles appear, in contrast to the grouped vesicles of recurrent attacks. When the skin of a limb is infected, vesicles appear in 2–3 days at the site of trauma. There is often centripetal spread along lymph channels, causing enlargement of regional lymph nodes and scattered vesicles on the intervening undamaged skin. This clinical picture may be mistaken for that of herpes zoster, especially if accompanied by neuralgic pain, unless the lesions are recognized as not being confined to a dermatome. The lesions heal slowly, often taking 3 wk. Recurrences at the site of local trauma are common and may assume a bullous pattern. Wrestlers, and also medical personnel, are prone to herpetic infections of superficial abrasions, which is known as **herpes gladiatorum**. HSV infection of minor trauma about the nails that leads to extremely painful, deep-seated spreading lesions with vesicles is known as **herpetic whitlow**. These lesions resolve spontaneously in 2–3 wk. Similar lesions occur on the fingers of thumb suckers who are suffering from herpetic gingivostomatitis. The lesions must be differentiated from bacterial infection. They should not be incised because incision may facilitate systemic spread of HSV.

ACUTE HERPETIC GINGIVOSTOMATITIS.

Oral HSV primary infection, probably the most common cause of stomatitis in children 1–3 yr of age, can also occur in older children and adults. The symptoms may appear abruptly, with pain in the mouth, salivation, fetor oris, refusal to eat, and fever, often as high as 40–40.6°C (104–105°F). Fever and irritability may precede the oral lesions by 1–2 days. The initial lesion is a vesicle (Fig. 231–1), which is seldom seen because of its early rupture. The residual lesion is 2–10?mm in diameter and is covered with a yellow-gray membrane (Fig. 231–2). When this membrane sloughs, a true ulcer remains. Although the tongue and cheeks are most commonly involved, no part of the oral lining is exempt. Except in edentulous infants, acute gingivitis is characteristic of the disease and may precede the appearance of mucosal vesicles. Submaxillary lymphadenitis is common. The

Figure 231-1 Vesicular lesions of herpetic stomatitis on the tongue.

acute phase lasts 4–9 days and is self-limited. Pain tends to disappear 2–4 days before healing of the ulcers is complete. In some instances the tonsillar regions are involved early and appear exudative, and acute tonsillitis of bacterial origin or enterovirus-induced herpangina may be suspected. Negative cultures for group A streptococcus and other bacterial pathogens and failure of the lesion to respond to antibiotic therapy differentiate a bacterial infection. The spread of the vesiculation to the buccal mucosa and anterior portion of the mouth is atypical for herpangina. A rare but serious complication of HSV gingivostomatitis is bacteremia with oral flora such as group A streptococcus and *Kingella*.

RECURRENT STOMATITIS AND HERPES LABIALIS.

The typical oral recurrence of HSV is one or a few vesicles grouped at the mucocutaneous junction. Lesions are usually accompanied by local pain, tingling, or itching and last 3–7 days. Systemic symptoms are unusual. Less commonly, localized lesions may occur on the palate in association with a febrile illness or on the mucosa adjacent to a lesion on the lip. Recurrent aphthous ulcers, however, are not caused by HSV. In some persons a generalized stomatitis recurs consistently 7–10 days after a recurrent herpetic lesion of the lip or elsewhere and is often accompanied by skin lesions of erythema multiforme. Indeed, recurrent HSV infection is one of the most common causes of recurrent erythema multiforme.

ECZEMA HERPETICUM (KAPOSI VARICELLIFORM ERUPTION).

This, the most serious manifestation of “traumatic herpes,” results from a widespread infection of the eczematous skin with HSV. The severity of this complication varies; the lesion

Figure 231-2 Herpetic stomatitis with vesicular-pustular lesions on the gingival mucosa.

may be so mild as to be overlooked, or it may be fatal. In a typical severe primary attack, vesicles develop abruptly in large numbers over the area of eczematous skin. They continue to appear in crops for as long as 7–9 days. Isolated at first, they later become grouped and may occur on adjoining areas of normal skin (Fig. 231–3). Wide denudation of the epidermis may occur. Scabs eventually form, and epithelialization occurs. The systemic reaction varies, but temperatures of 39.4–40.6°C (103–105°F) for 7–10 days are not uncommon. Recurrent attacks develop on chronic atopic skin lesions. Death may result from profound physiologic disturbances from loss of fluid, electrolytes, and protein through the skin; from dissemination of the virus to the brain and other organs; or from secondary bacterial invasion usually with *Staphylococcus* or group A streptococcus. Differentiation from eczema vaccinatum can usually be established by determining that the child has not been exposed to vaccinia and by the occurrence of crops of vesicles in herpes. The diagnosis can be confirmed by examination and culture of vesicular fluid.

OCULAR INFECTIONS.

Conjunctivitis and keratoconjunctivitis may occur as manifestations of either a primary or a recurrent infection. The conjunctiva appears congested and swollen, but there is little, if any, purulent discharge. In primary infection the preauricular node is usually enlarged and tender. Cataracts, uveitis, and chorioretinitis have been described in newborns and in the immunocompromised.

Corneal lesions may be superficial, in the form of a dendritic ulcer, or deep, as a disciform keratitis. Dendritic keratitis is unique to HSV eye involvement. The

diagnosis is suggested by the presence of herpetic vesicles on the lids; it is established by the isolation of the virus. Topical corticosteroid use will worsen HSV ocular disease. The highly contagious **epidemic keratoconjunctivitis** (shipyard conjunctivitis) caused by any of several serotypes of adenovirus- or enterovirus-induced conjunctivitis must be considered in the differential diagnosis. Recurrent herpetic corneal infection may result in scarring of the cornea and vision impairment.

GENITAL HERPES.

Genital infections with herpesvirus occur most commonly in adolescents and young adults, are usually due to HSV-2, and are usually spread by sexual activity.

Figure 231-3 Eczema herpeticum (Kaposi varicelliform eruption).

Although hand-to-genital transmission and autoinoculation are possible, genital or rectal herpes in a young child warrants a sensitive and careful appraisal of the possibility of child abuse. From 10 to 25% of primary genital herpes is caused by HSV-1. Most cases of recurrent genital herpes are due to HSV-2. In primary genital infection, when the patient has no antibody to either type of herpes, systemic symptoms such as fever, regional lymphadenopathy, and dysuria are more likely to occur. In adult women, the vulva and vagina may be involved with vesicles and ulcers, but the cervix is the primary site of infection. Recurrence is common. Both primary and recurrent disease are frequently subclinical, but virus shed during this time may infect a sex partner or an infant during passage through the birth canal. In males, herpetic vesicles or ulcers are usually seen on the glans penis, prepuce, or shaft of the penis. The scrotum is less frequently involved. Genital HSV is a risk factor for HIV infection.

CENTRAL NERVOUS SYSTEM INFECTIONS.

HSV has a predilection to infect the nervous system. Both types 1 and 2 may cause a meningoencephalitis as part of neonatal HSV. In patients with primary genital herpes, usually resulting from HSV-2, an aseptic meningitis syndrome may complicate the course. The cerebrospinal fluid (CSF) reveals a lymphocytic pleocytosis, and the virus may be cultured from it in patients with this self-limited syndrome. HSV-1 is an unusual cause of the aseptic meningitis syndrome, but it is the most common cause of fatal sporadic encephalitis. It has a striking predilection to involve the frontal and parietal areas. Typical signs and symptoms include fever, altered consciousness, headache, personality changes, seizures, dysphasia, and focal neurologic signs. If untreated, the mortality rate is 75%, with severe sequelae in survivors. HSV is the cause of most cases of recurrent aseptic meningitis (Mollaret meningitis), based on demonstration of HSV DNA in the CSF by polymerase chain reaction (PCR).

IMMUNOCOMPROMISED PERSONS.

Unusually severe HSV infection may occur in a variety of persons, including the newborn; the severely malnourished; and children with malignancies or other conditions necessitating immunosuppressive therapy, with AIDS, with burns, or with primary immunodeficiency diseases that particularly impair cell-mediated immunity. In children receiving therapy for cancer or organ transplantation, the risk of severe HSV infection coincides with the time of maximum immunosuppression. The most common syndrome is local and chronic oral or genital mucocutaneous disease. The lesions may resemble typical vesicles and ulcers or progress to large necrotic painful erosions or atypical exophytic, wart-like lesions. Mucositis, esophagitis, proctitis, and pneumonitis are less common. The most severe manifestation, usually a result of primary infection in the immunocompromised child, is widespread disseminated disease involving the liver, lungs, adrenal gland, and CNS. These patients have a sepsis-like syndrome with leukopenia, hepatitis, disseminated intravascular coagulopathy, fever, or hypothermia and progression to death. Skin lesions may be localized to mucous membranes, widely disseminated, resembling varicella infection, or absent. This form of HSV infection has a high mortality rate even with therapy.

PERINATAL INFECTIONS.

Most cases of neonatal herpes occur due to maternal infection during delivery, and approximately 75% are HSV type 2. At delivery, 0.2–0.4% of women shed HSV in their genital tract, which increases to 1–2% if there is a history of maternal genital herpes. The classification of maternal genital disease predicts the attack rate in newborns. Maternal primary or first episode genital herpes (no antibody present against the type of virus shed) has an infant attack rate of 33–50%. Recurrent maternal disease has an infant attack rate of only 1–3%. Only 15–20% of women with infants with neonatal herpes have a history of HSV infection, and only approximately 25% have some relevant symptoms at delivery. Intrapartum monitoring may be a risk factor; 40% of neonates with HSV infection had fetal scalp electrodes placed during delivery.

Rarely, in about 5% of cases, true intrauterine infection occurs. About 10% of infants acquire their infection postpartum, not necessarily from the mother, but also from another close family member shedding HSV (often type 1), from fever blisters, finger infections, or lesions at other sites.

Perinatal infection manifests in the first month of life, with 9% on the first day, and in 40% by the first week. There are 3 major categories: (1) localized skin, eye, and mouth infection; (2) CNS infection; and (3) disseminated infection. Localized skin, eye, and mouth infection and also disseminated infection occur at a mean of 5–6 days postpartum, whereas localized CNS infection occurs later at a mean of 8–12 days postpartum. The hallmark of neonatal HSV infection—the vesicular, ulcerative skin lesions (Fig. 231–4)—is present in only 30–43% of children at presentation; one third will never manifest skin lesions. Symptoms of CNS involvement are found in 48–79% and include lethargy, poor feeding, irritability, poor tone, and seizures. Fever (7–14%) and respiratory distress (5–19%) may also be present.

Particular attention should be directed to sites of fetal monitoring for the signs of pustular-vesicular infection, especially if unresponsive to antibiotics, and to the eyes for signs of herpetic keratoconjunctivitis. Approximately 70% of neonates with localized infection that is not treated will progress to CNS or disseminated disease.

The typical 5–7-day delay in diagnosis of neonatal HSV must be shortened if outcome is to improve.

Neonatal HSV infection should be considered in any neonate with suggestive signs born to a parent (mother or father) with a history of genital herpes; sepsis unresponsive to antibiotics especially with thrombocytopenia, elevated liver function tests, disseminated intravascular coagulopathy, or early pneumonitis; unexplained neonatal lymphocytic meningitis; unexplained hepatitis; or unexplained vesicular-ulcerative cutaneous eruption. These neonates must be treated for HSV pending diagnostic evaluation.

The infant born with a congenital infection syndrome, especially with skin vesicles or scars, chorioretinitis, microphthalmia, and microcephaly, should be evaluated for both congenital HSV and varicella, as well as other causes of congenital infection.

The risk of mortality due to treated HSV increases with CNS (6%) or disseminated (31%) disease. It is also increased in infants with coma, disseminated intravascular coagulopathy, prematurity, and pneumonitis. Morbidity among survivors increases with CNS or disseminated diseases, seizures, infection with type 2 virus, and frequent cutaneous recurrences.

The differential diagnosis of a vesicular-ulcerative eruption in the neonate is extensive (Table 231–1). Often an experienced pediatric dermatologist is invaluable help for diagnosis of some of the more arcane syndromes listed.

Figure 231-4 Vesicular-pustular lesions on the face of a neonate with herpes simplex virus infection. (From Kohl S: Neonatal herpes simplex virus infection. *Clin Perinatol* 1997;24:129–50.)

TABLE 231-1 -- **Differential Diagnosis of Vesicular Eruptions in the Neonate**

Infectious Etiologies	
Herpes simplex virus	*Aspergillus*
Staphylococcus aureus	Varicella-zoster virus
Pseudomonas	Cytomegalovirus
Haemophilus influenzae type b	*Listeria monocytogenes*
Treponema pallidum	Group B streptococcus
Candida	
Noninfectious Conditions	
Erythema toxicum	Herpes gestationis
Pustular melanosis	Incontinentia pigmenti
Miliaria	Neonatal lupus
Letterer-Siwe disease	Epidermolysis bullosa
Urticaria pigmentosa	Epidermolytic hyperkeratosis
Bullous mastocytosis	Acropustulosis
Dermatitis herpetiformis	Neonatal bullous dermatitis
Pemphigus vulgaris	Langerhans cell histiocytosis
Data from Case records of the Massachusetts General Hospital. Weekly clinicopathological exercises. N Engl J Med 1989;320:1399–410; 1996;334:1591–7.	
From Kohl S: Neonatal herpes simplex virus infection. Clin Perinatol 1997;24:129–50.	

Diagnosis.

The diagnosis is based on any two of the following: (1) a compatible clinical pattern; (2) isolation of the virus; (3) development of specific antibodies; and (4) demonstration of characteristic cells, histologic changes, viral antigen, or HSV DNA in scrapings, CSF, or biopsy material. A rise in CSF HSV antibody occurs in HSV encephalitis, but it is late in the illness and is useful only for retrospective diagnosis. HSV serologic changes (fourfold rise or seroconversion from negative to positive) usually occur after the critical period for diagnosis and therapy. Illnesses resulting from HSV recurrence may not demonstrate a diagnostic serologic rise, and neonates or severely immunocompromised individuals may fail to produce antibody during primary infection. Reliable antibody tests to differentiate serologic response to HSV-1 from HSV-2 are now commercially available. HSV-1 and HSV-2 viral isolates may be typed by a variety of readily available antigen (ELISA, fluorescent antibody) and molecular techniques. HSV isolates that are unrelated epidemiologically are all slightly different at the nucleic acid level, as discerned by DNA endonuclease restriction analysis. Using this technique, available in research laboratories only, it is possible to confirm infection of one individual by another and to demonstrate that apparent nosocomial outbreaks or viral transmission may instead represent a chance collection of unrelated cases, which could be extremely important for counseling and medicolegal reasons.

The use of PCR analysis of CSF and perhaps blood is critical to diagnose neonatal HSV infection, especially in the absence of skin lesions. The sensitivity of CSF PCR in neonatal CNS infection is 75%. Serology is not a useful tool for rapid diagnosis of

HSV infection in the neonate, as in the older child, because of transplacental maternal antibodies; MRI of the brain is often abnormal in neonates with CNS involvement and suggestive of HSV infection. CSF PCR is the only practical test, short of brain biopsy, to diagnose HSV encephalitis beyond the neonatal period, with a sensitivity and specificity of over 95%.

LABORATORY FINDINGS.

Microscopic examination of scrapings from lesions (Tzanck stain) reveals multinuclear giant cells and intranuclear inclusions approximately 50% of the time. Specific antigen detection methods such as ELISA and immunofluorescent techniques applied to these specimens can be useful in rapidly diagnosing herpes infection and in differentiating the two types of herpes. Virus can be readily isolated from vesicles and from conjunctival swabs in 1–4 days. The CSF is

---

positive for virus in about one third of infected neonates but is rarely positive in older children with encephalitis. PCR permits detection of viral DNA in CSF and, if positive, will make brain biopsy unnecessary. Brain biopsy may be necessary if PCR is negative for definitive diagnosis and exclusion of other treatable entities. At this time, PCR for HSV is available through specialized laboratories only.

Moderate polymorphonuclear leukocytosis occurs in acute herpetic gingivostomatitis, eczema herpeticum, and meningoencephalitis. In meningoencephalitis there are frequently red cells in the CSF and an increase in lymphocytes, usually below $100/mm^3$ but occasionally up to $1,000/mm^3$; the protein level is elevated, and the glucose is usually within the normal range but may be reduced. Electroencephalography (EEG) and MRI may demonstrate a temporal lobe lesion in early encephalitis. CT may be normal in early encephalitis but becomes abnormal as the disease progresses. Thrombocytopenia and elevated levels of liver function tests often occur with systemic infection.

Treatment.

Acyclovir (9-[-2-hydroxyethoxymethyl] guanine, a purine nucleoside analog) is the mainstay of therapy for HSV. Viral thymidine kinase phosphorylates acyclovir, which is then triphosphorylated by cellular enzymes to act as an HSV DNA polymerase inhibitor and DNA chain terminator. Thymidine kinase-negative HSV isolates are resistant to acyclovir.

Two more recently licensed oral anti-herpes drugs simplify the therapy for genital herpes. Valacyclovir, a prodrug of acyclovir, and famciclovir, a prodrug of penciclovir, have excellent oral bioavailability (55–80%) and are converted in vivo to acyclovir and penciclovir, respectively. As with acyclovir, penciclovir is phosphorylated by HSV thymidine kinase and then cellular enzymes to the triphosphate active agents. Due to excellent oral adsorption these drugs may be used less frequently than acyclovir. The ease of use is offset by the increased cost compared with generic acyclovir. Ongoing studies using famciclovir in immunocompromised persons show that larger oral doses reach serum levels obtained with intravenous acyclovir, and have facilitated oral therapy and prophylaxis of more severe forms of HSV infection.

Acyclovir-resistant HSV is rare in the normal host but occurs in the immunocompromised host treated with long-term or multiple, intermittent courses of acyclovir. When immunocompromised patients have unresponsive or worsening HSV infection despite acyclovir therapy, the virus should be forwarded to reference laboratories for drug susceptibility testing. Pending laboratory results (resistance to acyclovir is associated with inhibitory levels >2?µg/mL), the drug of choice for acyclovir-resistant HSV is intravenous foscarnet (phosphonoformic acid; 40?mg/kg/dose q 8?hr IV). This drug has serious adverse effects including azotemia, electrolyte disturbance, anemia, and granulocytopenia. Cidofovir has been successfully used in a small number of cases of acyclovir- and foscarnet-resistant virus. Acyclovir and foscarnet dosages must be modified in patients with renal impairment.

Topical acyclovir therapy for oral or genital herpes may decrease the period of viral shedding but has little effect on symptoms and is not recommended. Topical penciclovir, another nucleoside analog, reduces symptoms of oral recurrent herpes only modestly.

Topical trifluorothymidine, vidarabine, and idoxuridine are all usually effective in treating herpetic keratitis but do not reduce the recurrence rate. Topical corticosteroids may increase ocular involvement, if used alone, and should only be used with antiviral therapy.

The child or adolescent with recurrent oral or genital herpes may experience psychologic problems and may benefit from anticipatory guidance or formal counseling. Genital disease should be destigmatized, and safer sex practices emphasized. Parents of children with most types of HSV infection, such as gingivostomatitis or skin infection, should be reassured that common childhood HSV infections are not related to sexual activity or abuse.

SKIN AND MUCOUS MEMBRANES.

Oral acyclovir (15?mg/kg/dose five times a day with a maximum dose of 1?g/24?hr for 7 days) started within 72?hr of onset of lesions has significant benefits in children with primary herpetic gingivostomatitis by decreasing drooling, gum swelling, pain, eating and drinking difficulties, and duration of lesions. Therapy for recurrent oral herpes with oral acyclovir has limited effect.

Symptomatic and supportive therapy is of great importance. Oral lavage should be used for mouth care; Ceepryn 1:4,000 or Zephiran 1:1,000 may be useful. Local analgesics, such as viscous lidocaine or benzocaine lozenges, are not advocated because they may cause the child to damage friable and anesthetized parts of the mouth. Food and fluid intake will be facilitated by acquiescing to the child's whims. Ice-cold fluids, ice slush, or semisolids are often accepted when other food is refused. In infants especially, eczema herpeticum and stomatitis may lead to severe dehydration, shock, and hypoproteinemia, requiring intravenous replacement of fluids, electrolytes, and proteins.

Acyclovir has no effect on HSV-associated erythema multiforme. Suppression of the HSV infection by prophylactic therapy as for genital disease prevents the erythema multiforme recurrences.

Oral acyclovir is beneficial for treating primary and recurrent herpes whitlow and rectal herpes.

GENITAL HERPES.

Patients with primary genital infection who are treated with oral acyclovir have significantly less pain, itching, and time to crusting; a shorter duration of viral shedding; and fewer new lesions compared with control patients. Those with recurrent genital infections who are treated similarly with oral acyclovir have a shorter duration of viral shedding and heal faster. Therapy for primary attacks does not prevent recurrences. However, daily prophylactic administration of oral acyclovir can diminish the number of recurrences and may be prescribed if recurrences are frequent or severe.

The recommended treatment regimen for initial genital herpes in older adolescents and adults is valacyclovir (1,000?mg/dose bid PO for 7–10 days) or famciclovir (250?mg/dose tid PO for 7–10 days); these are equivalent to acyclovir (200?mg/dose 5 times a day PO). For HSV genital recurrence, valacyclovir (500?mg/dose bid PO for 5 days) and famciclovir (125?mg/ dose bid PO for 5 days) are equivalent to acyclovir (400?mg/dose tid or 200?mg/dose 5 times a day PO). Daily suppressive therapy reduces the frequency of genital herpes recurrences by 75% or more among persons with 6 or more recurrences per year. Recommended regimens for daily suppressive therapy in older adolescents and adults are famciclovir (125?mg/dose or 250?mg/dose bid PO), valacyclovir (500?mg/dose or 1000?mg/ dose PO once daily), or acyclovir (400?mg/dose bid or tid PO). The child dose of acyclovir for primary genital HSV is 10–20?mg/ kg/dose qid PO, not to exceed adult dosage. There are no pediatric dosage regimens of valacyclovir or famciclovir.

Genital lesions may be made less painful by using sitz baths. Local drying agents prolong healing and may increase secondary infection. Analgesics should be used systemically as required. Antibiotics are useful only in treating secondary bacterial infections.

CENTRAL NERVOUS SYSTEM AND SYSTEMIC INFECTIONS.

Intravenously administered acyclovir (10?mg/kg/dose given over 1?hr q 8?hr IV for 14–21 days) is the treatment of choice for herpes encephalitis. The drug is well tolerated. The best results are obtained when treatment is started early. Patients younger than 30 yr of age and those who are only lethargic compared with those who have progressed to coma have a better prognosis. Supportive care to minimize increased intracranial pressure, seizure activity, and respiratory compromise requires an intensive care setting and a team of experts.

Intravenous acyclovir (5–10?mg/kg/dose given over 1?hr q 8?hr, with the duration depending on clinical response) is recommended for treatment of HSV infections in the immunocompromised host. The larger doses are used for severe and systemic infections. The lower dose may be used for localized mucocutaneous disease. As the patient responds, therapy may be switched to the oral route. Oral acyclovir, as used in genital disease, may be used to suppress HSV recurrences in seropositive patients during periods of maximum immunosuppression after organ or marrow transplantation or during induction therapy for leukemia, lymphoma, or solid tumors. Immunosuppressed patients with frequently recurring HSV infection, such as those with AIDS or primary immunodeficiencies, benefit from chronic suppressive oral therapy. Valacyclovir should not be used in immunocompromised children due to unusual adverse effects.

PERINATAL INFECTIONS.

As in other serious forms of HSV infection, intravenous acyclovir (20?mg/kg/dose q 8?hr for 14–21 days) is the drug of choice for neonatal HSV infection. This high dose of acyclovir may be associated with neutropenia. For the neonate with HSV infection, intensive care is necessary initially to observe for signs of disseminated or CNS disease necessitating ventilatory control, seizure management, and intensive supportive care. There is preliminary evidence to suggest extending therapy of HSV neonatal encephalitis for longer than 21 days until the HSV CSF PCR becomes negative. Preliminary data suggest that the use of daily oral acyclovir (300?mg/m^2 tid PO) for 6 mo can suppress the common cutaneous recurrences associated with poor outcome, but the effects on central nervous system infection and long-term prognosis are unproved. Recurrence of cutaneous infection soon after cessation of suppressive therapy is frequent. Prolonged treatment has been associated with neutropenia and the rare emergence of acyclovir-resistant virus.

Prognosis.

Primary localized infections with HSV in the normal host are self-limited, usually lasting 1–2 wk. Mortality rates are high in newborns who also have systemic infection and in older infants who are severely immunocompromised or malnourished. In patients with meningoencephalitis the prognosis for survival or for recovery without serious permanent residua is guarded. Outcome is improved with early diagnosis and therapy.

Attacks may frequently recur, but they seldom cause more than temporary inconvenience except in the eye, where they may eventually cause scarring of the cornea and blindness. Recurrent herpes lesions can be a significant problem in immunocompromised patients. Recurrent genital disease may be associated with significant discomfort and psychologic morbidity. The major complication of any form of genital HSV infection in a woman is infection of her newborn.

Prevention.

Acyclovir administered during periods of high risk in immunocompromised hosts and administered chronically in individuals with frequently recurrent genital or oral disease markedly decreases the rate of recurrence. Acyclovir administered before a known trigger factor, such as intense sunlight, usually prevents recurrences.

HSV spread can be limited by standard methods of infection control. Open lesions on skin, hands, and mucous membranes should be well covered. Wrestlers with possible HSV cutaneous lesions should be excluded from practice and competition until they are healed. Wrestling mats should be cleansed with a bleach solution at least daily. Children with immunodeficiencies or chronic skin diseases that predispose to severe HSV infection should not be cared for by persons with herpetic whitlow or active uncovered fever blisters. Active herpes lesions that can be covered are not a reason to exclude children from daycare or school activities.

There is active research to develop a vaccine to prevent HSV infection. HSV may be prevented in some animal models by live, attenuated, naked DNA, or subunit viral particle vaccines. Several purified HSV glycoprotein vaccines are antigenic in humans, but to date these vaccines have lacked consistent efficacy in clinical trials.

OBSTETRIC MANAGEMENT OF THE WOMAN WITH GENITAL HSV INFECTION.

The major aims of obstetric care of the woman with genital HSV infection are to ameliorate the symptoms of infection in the mother and to lessen the risk of neonatal HSV infection in the neonate. A reliable history of genital HSV infections must be determined for all women presenting for prenatal care.

Acyclovir is a pregnancy category C medication (should not be used during pregnancy unless the potential benefit justifies the potential risk to the fetus). In a registry of more than 600 women exposed to acyclovir during pregnancy, no increased rate of fetal malformations or unusual pattern of malformations has been noted, although this number is too low to detect a low-level or rare teratogenic effect. It is clear that primary HSV infection in the pregnant woman carries an increased risk of life-threatening dissemination, and intravenous acyclovir should be administered if there are any signs of disseminated HSV disease.

Recommendations of both the American Academy of Pediatrics and the American College of Obstetrics and Gynecology are for a cesarean section if primary, first-episode, or recurrent HSV lesions are present at the onset of labor (Box 231–1). This recommendation for recurrent infection is controversial: Given the low attack rate of HSV to the neonate in the case of maternal recurrent disease, nearly 1,600 excess cesarean deliveries will be performed for every prevention of poor neonatal outcome, at a cost of $2.5 million per case of neonatal herpes prevented and a possible excess of maternal deaths outnumbering prevented deaths in neonates.

If no lesions can be demonstrated at delivery, the child may be delivered via the vaginal route. For women with a history of recurrent genital herpes who have no obvious lesions at the time of delivery, it is not universally agreed that routine HSV cultures taken at delivery of mother or newborn are useful, although some experts advocate routine cultures. If cultures at delivery are positive for HSV, most experts recommend obtaining cultures from the neonate at 24–48?hr of life (eyes, mouth, urine, stool) and treating with acyclovir if any cultures are positive or if the neonate has any signs of HSV infection in the ensuing 4 wk.

Box 231-1. Management of the Child Born to a Woman with Active Genital HSV Infection

MATERNAL PRIMARY OR FIRST-EPISODE INFECTION

- Cesarean section within 24?hr (preferably 4?hr) of ruptured membranes
    - Culture eyes, nose, mouth, urine, and stool at 48?hr
    - Treat with acyclovir if any culture is positive or there are signs of neonatal HSV*
- Unavoidable vaginal delivery
    - Culture eyes, nose, mouth, urine, stool, and cerebrospinal fluid
    - Treat with acyclovir

RECURRENT INFECTION, ACTIVE AT DELIVERY

- Cesarean section within 24 (preferably 4) hours of ruptured membranes
    - Culture eyes, nose, mouth, urine, and stool at 48?hr
    - Treat with acyclovir if any culture is positive or there are signs of HSV infection*
- Unavoidable vaginal delivery
    - Culture eyes, nose, mouth, urine, and stool at 48?hr

Unavoidable vaginal delivery

Culture eyes, nose, mouth, urine, and stool at 48?hr

Treat with acyclovir if any culture is positive or there are signs of HSV infection*

From Kohl S: Neonatal herpes simplex virus infection. Clin Perinatol 1997;24:129–50.

*If the infant is to be treated with acyclovir, cerebrospinal fluid analysis, culture, and polymerase chain reaction test for HSV DNA are indicated.

For pregnant women with a history of genital herpes, there are preliminary data to demonstrate that suppressive acyclovir therapy administered near delivery reduces viral shedding and the need for cesarean section. This strategy of prophylactic maternal acyclovir needs further confirmation before it can be universally recommended.

Primary and first-episode genital infections are probably associated with some increased risk of spontaneous abortion, and with increased risk of premature delivery of 30–50%. Intrauterine infection is a rare consequence of genital infection.

In the neonate inadvertently born vaginally to a woman with active primary or first-episode HSV infection, positive cultures at 24–48?hr of life (eyes, mouth, urine, stool, and CSF), abnormal CSF findings, or any signs of HSV in the first 4 wk of life mandate acyclovir therapy (see Box 231–1). Many experts recommend anticipatory use of acyclovir therapy after delivery in this setting because of the high attack rate, although there are no data that demonstrate reduction of neonatal infection, and several case reports had demonstrated failure of early neonatal therapy.

Cesarean section is not completely protective, because 20–30% of infants with neonatal HSV infection are born by abdominal delivery. Thus, all newborns of women with primary or first-episode genital HSV infection also should have cultures taken at 48?hr of life and be followed for signs of infection regardless of the route of delivery.

Most women who are delivered of a neonate with HSV infection are not aware of their own HSV infection and usually have no symptoms at delivery. It also may be difficult to determine clinically if a genital infection at delivery represents a recurrence or a more severe primary or first-episode infection. Determination of serologic status of these women and their partners with type-specific antibody, and a rapid antigen or PCR strategy for genital viral detection, may be useful in the future.

Chapter 232 - Varicella-Zoster Virus

Martin G. Myers
Lawrence R. Stanberry
Jane F. Seward

Varicella-zoster virus (VZV) causes primary, latent, and recurrent infections. The primary infection is manifested as varicella (chickenpox) and results in establishment of a lifelong latent infection of sensory ganglion neurons. Reactivation of the latent infection causes herpes zoster (shingles). Although often a mild illness of childhood, chickenpox can cause substantial morbidity and mortality in otherwise healthy children; it causes increased morbidity and mortality in adolescents, adults and immunocompromised persons and predisposes to severe group A streptococcus and *Staphylococcus aureus* infections. Chickenpox and zoster can be treated with antiviral drugs. Infection can be prevented by immunization with live-attenuated VZV vaccine. Gestational chickenpox can be severe in the mother and can cause a rare but distinct intrauterine syndrome. Chickenpox in the newborn can be severe and life threatening.

Etiology.

VZV is a neurotropic human herpesvirus with similarities to herpes simplex virus, which is also an a-herpesvirus. These viruses are enveloped with double-stranded DNA genomes that encode more than 70 proteins, including proteins that are targets of cellular and humoral immunity.

Epidemiology.

Prior to the introduction of vaccine in 1995, varicella was an almost universal communicable infection of childhood in the United States. Most children were infected by 15 yr of age, with fewer than 5% of adults remaining susceptible. Annual varicella epidemics occurred in winter and spring, accounting for about 4 million cases, 11,000 hospitalizations, and 100 deaths every year. Varicella is a more serious disease with higher rates of complications and deaths among infants, adults, and immunocompromised persons. Within households, transmission of VZV to susceptible individuals occurs at a rate of 65–86%; more casual contact, such as occurs in a school classroom, is associated with lower attack rates among susceptible children. Patients with varicella are contagious from 24–48?hr before the rash appears and until vesicles are crusted, usually 3–7 days after onset of rash.

Susceptible children may also acquire varicella after close, direct contact with adults or children who have herpes zoster. Varicella has declined substantially in areas with moderate to high levels of vaccine coverage; varicella that occurs among immunized children (so-called **breakthrough varicella**) is usually very mild.

Herpes zoster, because it is due to the reactivation of latent VZV, is uncommon in childhood and shows no seasonal variation in incidence. The lifetime risk for herpes zoster for individuals with a history of varicella is 10–15%, with 75% of cases occurring after 45 yr of age. Herpes zoster is very rare in healthy children younger than 10 years of age except for those infected in utero or in the first year of life; herpes zoster in children tends to be milder than disease in adults and is less frequently associated with postherpetic neuralgia. However, herpes zoster occurs more frequently, occasionally multiple times, and may be severe in children receiving immunosuppressive therapy for malignancy or other diseases and in those who have HIV infection.

Pathogenesis.

VZV is transmitted in respiratory secretions and in the fluid of skin lesions either by airborne spread or through direct contact. Primary infection (varicella) results from the respiratory inoculation of virus. During the early part of the 10–21-day incubation period, virus replicates in the respiratory tract followed by a brief subclinical viremia. Widespread cutaneous lesions occur during a second viremic phase. Peripheral blood mononuclear cells carry infectious virus, generating new crops of vesicles for 3–7 days. VZV is also transported back to respiratory mucosal sites during the late incubation period, permitting spread to susceptible contacts before the appearance of rash. Host immune responses limit viral replication and facilitate recovery from infection. In the immunocompromised child, the failure of immune responses, especially cell-mediated immune responses, results in continued viral replication with resultant injury to lungs, liver, brain, and other organs.

VZV establishes latent infection in sensory ganglia cells in all individuals who experience primary infection. Subsequent reactivation of latent virus causes herpes zoster, a vesicular rash that usually is dermatomal in distribution. During herpes zoster, necrotic changes may be produced in the associated ganglia. The skin lesions of varicella and herpes zoster have identical histopathology, and infectious VZV is present in both. Varicella elicits humoral and cell-mediated immunity that is highly protective against symptomatic re-infection. Suppression of cell-mediated

immunity to VZV correlates with an increased risk of VZV reactivation as herpes zoster.

Clinical Manifestations.

Varicella is an acute febrile rash illness, common in children who have not been immunized. It has variable severity but is usually self-limited. It may be associated with severe complications, including bacterial super-infection, pneumonia,

encephalitis, bleeding disorders, congenital infection, and life-threatening perinatal infection. Herpes zoster, uncommon in children, causes localized cutaneous symptoms, but may disseminate in immunocompromised patients.

VARICELLA.

The illness usually begins 14–16 days after exposure, although the incubation period can range from 10–21 days. Subclinical varicella is rare; almost all exposed, susceptible children experience a rash, but illness may be limited to only a few lesions. Prodromal symptoms may be present, particularly in older children. Fever, malaise, anorexia, headache, and occasionally mild abdominal pain may occur 24–48?hr before the rash appears. Temperature elevation is usually moderate, usually from 100–102℉ but may be as high as 106℉; fever and other systemic symptoms persist during the first 2–4 days after the onset of the rash.

Varicella lesions often appear first on the scalp, face, or trunk. The initial exanthem consists of intensely pruritic erythematous macules that evolve through the papular stage to form clear, fluid-filled vesicles. Clouding and umbilication of the lesions begin in 24–48?hr. While the initial lesions are crusting, new crops form on the trunk and then the extremities; the simultaneous presence of lesions in various stages of evolution is characteristic of varicella (Fig. 232–1). The distribution of the rash is predominantly central or centripetal in contrast to smallpox, where the rash is more prominent on the face and distal extremities. Ulcerative lesions involving the oropharynx and vagina are also common; many children have vesicular lesions on the eyelids and conjunctivae, but corneal involvement and serious ocular disease is rare. The average number of varicella lesions is about 300, but healthy children may have fewer than 10 to more than 1,500 lesions. In cases resulting from secondary household spread and in older children, more lesions usually occur, and new crops of lesions may continue to develop for a longer period of time. The exanthem may be much more extensive in children with skin disorders, such as eczema or recent sunburn. Hypopigmentation or hyperpigmentation of lesion sites persists for days to weeks in some children, but severe scarring is unusual unless the lesions were secondarily infected.

The differential diagnosis of varicella includes vesicular rashes caused by other infectious agents, such as herpes simplex virus, enterovirus, or *Staphylococcus aureus*; drug reactions; contact dermatitis; and insect bites. Severe varicella was the most common illness confused with smallpox before the eradication of this disease.

BREAKTHROUGH VARICELLA.

Vaccine is more than 95% effective in preventing typical varicella and is 70–90% effective

Figure 232-1 Skin lesions of chickenpox. Note the varying stages of development (macules, papules, and vesicles) present at the same time. (Courtesy of PF Lucchesi.)

at preventing all disease. Asymptomatic infection with wild-type virus may occur frequently in the previously immunized child. Breakthrough disease is varicella in a child vaccinated more than 42 days before rash onset and is due to wild-type VZV. Rash occurring within the first 2 weeks of vaccination is most commonly wild-type VZV, rash occurring 2–6 weeks after vaccination could be due to either the wild or vaccine strains. The rash in breakthrough disease is frequently atypical, predominantly maculopapular, vesicles are uncommon, being seen in only about 6% of cases, and the illness is most commonly mild with fewer than 50 lesions and little or no fever. Children with breakthrough disease should be considered potentially infectious and excluded from school until lesions have crusted or, if there are no vesicles present, until no new lesions are occurring. Transmission has been documented to occur from breakthrough cases in household, childcare, and school settings.

PROGRESSIVE VARICELLA.

Progressive varicella, with visceral organ involvement, coagulopathy, severe hemorrhage, and continued lesion development is a dreaded complication of primary VZV infection. Severe abdominal pain and the appearance of hemorrhagic vesicles in otherwise healthy adolescents and adults, immunocompromised children, pregnant women, and newborns may herald this. The risk of progressive varicella is highest in children with congenital cellular immune deficiency disorders and those with malignancy, particularly if chemotherapy was given during the incubation period and the absolute lymphocyte count is <500 cells/mm^3 . In one large series, the mortality rate for children who acquired varicella while undergoing treatment for malignancy and who were not treated with antiviral therapy was 7%. In this series all varicella-related deaths occurred within 3 days after the diagnosis of varicella pneumonia. Children who acquire varicella after organ transplantation are also at risk for progressive VZV infection. Children on long-term, low-dose systemic corticosteroid therapy are not considered to be at higher risk of severe varicella, but progressive varicella does occur in patients receiving high-dose corticosteroids and has been reported in patients receiving inhaled corticosteroids. Unusual clinical findings of varicella, including lesions that develop a unique hyperkeratotic appearance and the continued new lesion formation for weeks or months, have been described in children with HIV infection.

NEONATAL CHICKENPOX.

Newborns have particularly high mortality in the circumstances of a susceptible mother contracting varicella around the time of delivery. Birth within 1 wk before or after the onset of maternal varicella frequently results in the newborn developing varicella, which may be severe. The initial infection is intrauterine, although the newborn often develops clinical chickenpox postpartum. The risk to the newborn is dependent on the amount of maternal anti-VZV antibody that the fetus acquired transplacentally before birth. If there was 1 wk or greater interval between maternal chickenpox and parturition, it is likely that the newborn received sufficient transplacental antibody to VZV to ameliorate neonatal infection. Alternatively, if the interval was less than 1 wk, the newborn will be unlikely to have protective VZV antibody and neonatal chickenpox may be exceptionally severe.

The recommendations for varicella-zoster immune globulin (VZIG) reflect the differing risks to the exposed infant. Newborns whose mothers develop varicella 5 days before to 2 days after delivery should receive one vial. Although neonatal varicella may occur in about half of these infants despite administration of VZIG, it is usually mild. Every premature infant born to a mother with active chickenpox at

delivery (even if present > 1 wk) should receive VZIG. Because perinatally acquired varicella may be life threatening, it should be treated with acyclovir (10?mg/kg q 8?hr IV). Neonatal chickenpox can also follow a postpartum exposure of an infant delivered to a mother who was susceptible to VZV, although the frequency of complications declines rapidly in the weeks after birth. Infants with

community-acquired chickenpox who develop severe varicella, especially those who develop a complication such as pneumonia, hepatitis, or encephalitis, should also receive treatment with intravenous acyclovir (10?mg/kg q 8?hr IV).

CONGENITAL VARICELLA SYNDROME.

When pregnant women contract chickenpox, about 25% of the fetuses may become infected although not every infected fetus is clinically affected. However, up to 2% of fetuses whose mothers had varicella in the first 20 weeks of pregnancy may demonstrate VZV embryopathy. The period of greatest risk to the fetus correlates with the gestational period when there is major development and innervation of the limb buds and maturation of the eyes. Fetuses infected at 6–12 wk of gestation appear to have maximal interruption with limb development; fetuses infected at 16–20 wk may have eye and brain involvement. In addition, viral damage to the sympathetic fibers in the cervical and lumbosacral cord may lead to divergent effects such as Horner syndrome and dysfunction of the urethral or anal sphincters. Most of the stigmata can be attributed to virus-induced injury to the nervous system, although there is no obvious explanation why certain regions of the body are preferentially infected during fetal VZV infection. The stigmata involve mainly the skin, extremities, eyes, and brain (Box 232–1). The characteristic cutaneous lesion has been called a cicatrix, a zigzag scarring, often in a dermatomal distribution. The characteristic cicatricial scarring may represent the cutaneous residua of VZV infection of the sensory nerves, analogous to herpes zoster. The virus may select tissues that are in a rapid developmental stage, such as the limb buds. This may result in one or more shortened and malformed extremities (Fig. 232–2). Frequently, the atrophic extremity is covered with a cicatrix. The remainder of the torso may be entirely normal in appearance. Alternatively, there may be neither skin nor limb abnormalities but the infant may show cataracts or even extensive aplasia of the entire brain. Occasionally, calcifications are evident within a microcephalic head (Fig. 232–3). Histologic examination of the brain demonstrates necrotizing cerebral lesions involving the leptomeninges, the cortex, and the adjacent white matter.

Many infants with severe manifestations of congenital varicella syndrome have significant neurologic deficiencies, whereas those with only isolated stigmata, amenable to treatment, develop normally throughout childhood. Infants with neonatal chickenpox who receive prompt antiviral therapy have an excellent prognosis.

The diagnosis of VZV fetopathy is based mainly on the history of gestational chickenpox combined with the stigmata seen in the fetus. Virus cannot be cultured from the affected newborn, but viral DNA can be detected in tissue samples by PCR. Some

Box 232-1. Stigmata of Varicella-Zoster Virus Fetopathy

Damage to Sensory Nerves
- Cicatricial skin lesions
- Hypopigmentation

Damage to Optic Stalk and Lens Vesicle
- Microphthalmia
- Cataracts
- Chorioretinitis
- Optic atrophy

Damage to Brain/Encephalitis
- Microcephaly
- Hydrocephaly
- Calcifications
- Aplasia of brain

Damage to Cervical or Lumbosacral Cord
- Hypoplasia of an extremity
- Motor and sensory deficits
- Absent deep tendon reflexes
- Anisocoria
- Horner syndrome
- Anal/urinary sphincter dysfunction

Figure 232-2 Newborn with congenital varicella syndrome. The infant had severe malformations of

both lower extremities and cicatricial scarring over his left abdomen.

infants have VZV-specific IgM antibody detectable in the cord blood sample, although the IgM titer drops quickly postpartum. Chorionic villus sampling and fetal blood collection for the detection of viral DNA, virus, or antibody have been used in an attempt to diagnose fetal infection and embryopathy. The usefulness of these tests for patient management and counseling has not been defined. Because these tests may not distinguish between infection and disease, their utility may primarily be that of reassurance when the test is negative.

Although VZIG is often administered to the susceptible mother exposed to chickenpox, it is uncertain as to whether this modifies infection in the fetus. Similarly, acyclovir treatment may be given to the mother with severe varicella; however, neither its safety nor its efficacy for the fetus is known. The damage caused by fetal VZV infection does not progress postpartum, an indication that there is no persistent viral replication. Thus, antiviral treatment of infants with congenital VZV syndrome is not indicated.

HERPES ZOSTER.

Herpes zoster is manifested as vesicular lesions clustered within one or less commonly two adjacent dermatomes (Fig. 232–4). Unlike zoster in adults, zoster in children is infrequently associated with localized pain, hyperesthesias, pruritus, and low-grade fever. In children, the rash is mild, with new lesions appearing for a few days; symptoms of acute neuritis are minimal; and complete resolution usually occurs within 1–2 wk. In contrast to adults, postherpetic neuralgia is very unusual in children. Approximately 4% of patients suffer a second episode of herpes zoster; 3 or more episodes are rare. Transverse myelitis with transient paralysis is a rare complication of herpes zoster. An increased risk of herpes zoster early in childhood has been described in children who acquire varicella in the first year of life as well as in those whose mothers have a varicella infection in the third trimester of pregnancy.

Immunocompromised children may have more severe herpes zoster, which is similar to that in adults, including postherpetic neuralgia. Immunocompromised patients may also experience disseminated cutaneous disease that mimics varicella, as well as

Figure 232-3 Magnetic resonance image of newborn with encephalitis secondary to congenital varicella syndrome. The intrauterine infection occurred about 3 mo antepartum, at which time there was extensive necrosis of the cerebral hemispheres. The image of the newborn head was taken with the patient supine; therefore, there is a fluid/fluid interface in the dependent occiput (A). The hydrocephalus (C) and calcifications in the basal ganglia (D) are visible; a cranial artifact (B) is seen secondary to a scalp vein needle.

visceral dissemination with pneumonia, hepatitis, encephalitis, and disseminated intravascular coagulopathy. Severely immunocompromised children, particularly those with HIV infection, may have unusual, chronic, or relapsing cutaneous disease, retinitis, or central nervous system disease without rash. A lower risk of herpes zoster in vaccinated children with leukemia compared with those who have had varicella disease suggests that varicella vaccine virus reactivates less commonly than wild-type VZV.

Diagnosis.

Laboratory evaluation has not been considered necessary for the diagnosis or management of healthy children with

Figure 232-4 Herpes zoster.

varicella or herpes zoster. However, as disease declines to low levels, laboratory confirmation of all varicella cases will become necessary. Leukopenia is typical during the first 72 hours; it is followed by a relative and absolute lymphocytosis. Results of liver function tests are also usually (75%) mildly elevated. Patients with neurologic complications of varicella or uncomplicated herpes zoster have a mild lymphocytic pleocytosis and a slight to moderate increase in protein in the cerebrospinal fluid; the glucose concentration is usually normal.

Unusual or very severe varicella in otherwise immunocompetent individuals must be distinguished from smallpox, which may occur following deliberate release of smallpox virus (Chapter 706). A suspected case of smallpox should be reported immediately to the local and state health departments. A protocol for evaluating patients with acute vesicular-pustular rash illness for the possibility of smallpox is available on the CDC website at www.cdc.gov/nip/.

Rapid laboratory diagnosis of VZV is often important in high-risk patients and is sometimes important for infection control. Confirmation of varicella (or herpes simplex virus) can be accomplished by most referral hospital laboratories. VZV can be identified quickly by direct fluorescence assay (DFA) of cells from cutaneous lesions, which is widely available, and by polymerase chain reaction (PCR) amplification testing. Although multinucleated giant cells can be detected with nonspecific stains (**Tzanck smear**), they have poor sensitivity and do not differentiate VZV and herpes simplex virus infections. Infectious virus may be recovered using tissue culture methods; newer methods have decreased time needed for culture from 7–10 days to 3–4 days. VZV immunoglobulin G (IgG) antibodies can be detected by several methods and a 4-fold rise in IgG antibodies is also confirmatory of acute infection. VZV IgG antibody tests can also be valuable to determine the immune status of individuals whose clinical history of varicella is unknown or equivocal. Testing for VZV IgM antibodies is not useful for clinical diagnosis because commercially available methods are unreliable. A capture IgM assay is available at the national VZV laboratory at CDC

Treatment.

Antiviral treatment modifies the course of both varicella and herpes zoster. Antiviral drug resistance is rare but has occurred in children with HIV infection who have been treated. Foscarnet is the only drug now available for the treatment of acyclovir-resistant VZV infections.

VARICELLA.

The only antiviral drug available in liquid formulation and that is licensed for pediatric use is acyclovir. Given the safety profile of acyclovir and its demonstrated efficacy in the treatment of varicella, treatment of all children, adolescents, and adults with varicella is acceptable. However, acyclovir therapy is not recommended routinely by the American Academy of Pediatrics for treatment of uncomplicated varicella in the otherwise healthy child because of the marginal benefit, the cost of the drug, and the low risk of complications. Oral therapy with acyclovir (20?mg/kg/dose; maximum: 800?mg/dose) given as 4 doses per day for 5 days should be used to treat uncomplicated varicella in nonpregnant individuals 13 yr of age or older and children 12 mo of age or older with chronic cutaneous or pulmonary disorders; receiving short-term, intermittent, or aerosolized corticosteroids; receiving long-term salicylate therapy; and possibly second cases in household contacts. To be most effective, treatment should be initiated as early as possible, preferably within 24?hr of the onset of the exanthem. There is dubious clinical benefit if initiation of treatment is delayed more than 72?hr after onset of the exanthem. Acyclovir therapy does not interfere with the induction of VZV immunity. Intravenous therapy is indicated for severe disease and for varicella in immunocompromised patients. Acyclovir has been used to treat varicella in pregnant women; however, its safety for the fetus has not been established. Any patient who has signs of

disseminated VZV including pneumonia, severe hepatitis, thrombocytopenia, or encephalitis should receive immediate treatment. Intravenous acyclovir (500?mg/m^2 q 8?hr IV) therapy initiated within 72?hr of development of initial symptoms decreases the likelihood of progressive varicella and visceral dissemination in high-risk patients. Treatment is continued for 7 days or until no new lesions have appeared for 48?hr. Delaying antiviral treatment until prolonged new lesion formation is evident is not advisable because visceral dissemination occurs during the same time period.

HERPES ZOSTER.

Antiviral drugs are effective for treatment of herpes zoster. In healthy adults, acyclovir (800?mg 5 times a day PO for 5 days), famciclovir (500?mg tid PO for 7 days), and valacyclovir (1,000?mg tid PO for 7 days) reduce the duration of the illness and the risk of developing postherpetic neuralgia; concomitant corticosteroid usage improves the quality of life in the elderly. In otherwise healthy children, however, herpes zoster is a less severe disease, and postherpetic neuralgia is rare. Therefore, treatment of uncomplicated herpes zoster in the child with an antiviral agent may not always be necessary, although some experts would treat with oral acyclovir (20?mg/kg/dose; maximum 800?mg/dose) to shorten the duration of the illness. Use of corticosteroids for herpes zoster in otherwise healthy children is not recommended.

In contrast, herpes zoster in immunocompromised children can be severe and disseminated disease may be life threatening. Patients at high risk for disseminated disease should receive acyclovir (500?mg/m^2 or 10?mg/kg q 8?hr IV). Oral acyclovir is an option for immunocompromised patients with uncomplicated herpes zoster and who are considered at low risk for visceral dissemination.

Complications.

The complications of VZV infection occur with varicella, or with reactivation of infection, more commonly in immunocompromised patients. In the otherwise healthy child, mild varicella hepatitis is relatively common but rarely clinically symptomatic. Mild thrombocytopenia occurs in 1–2% of children with varicella and may be associated with transient petechiae. Purpura, hemorrhagic vesicles, hematuria, and gastrointestinal bleeding are rare complications that may have serious consequences. Cerebellar ataxia occurs in 1 in every 4000 cases. Other complications, some of them rare, of varicella include encephalitis, pneumonia, nephritis, nephrotic syndrome, hemolytic-uremic syndrome, arthritis, myocarditis, pericarditis, pancreatitis, and orchitis.

BACTERIAL INFECTIONS.

Secondary bacterial infections of the skin, usually caused by *Streptococcus* and *Staphylococcus,* may occur in up to 5% of children with varicella. These range from superficial impetigo to cellulitis, lymphadenitis, and subcutaneous abscesses. An early manifestation of secondary bacterial infection is erythema of the base of a new vesicle. Recrudescence of fever 3–4 days after the initial exanthem may also herald a secondary bacterial infection. Varicella is a well-described risk factor for serious infections caused by group A streptococcus. The more invasive infections, such as varicella gangrenosa, bacterial sepsis, pneumonia, arthritis, osteomyelitis, and necrotizing fasciitis, account for much of the morbidity and mortality of varicella in otherwise healthy children. Bacterial toxin–mediated diseases (e.g., toxic shock syndrome) also may complicate varicella.

ENCEPHALITIS AND CEREBELLAR ATAXIA.

Encephalitis and acute cerebellar ataxia are well-described neurologic complications of varicella; morbidity from central nervous system complications is highest among patients younger than 5 yr or older than 20 yr of age. Nuchal rigidity, altered consciousness, and seizures characterize meningoencephalitis. Patients with cerebellar ataxia have a gradual onset of gait disturbance, nystagmus, and slurred speech. Neurologic symptoms usually begin 2–6 days after the onset of the rash but may occur during the incubation period or after resolution of the rash. Clinical recovery is typically rapid, occurring within 24–72?hr, and is usually complete. Although severe hemorrhagic encephalitis, analogous to that caused by herpes simplex virus, is very rare in children with varicella, the consequences are similar to herpes encephalitis. Reye syndrome of encephalopathy and hepatic dysfunction associated with varicella has become rare since salicylates are no longer routinely used as antipyretics (Chapter 342).

PNEUMONIA.

Varicella pneumonia is a severe complication that accounts for most of the increased morbidity and mortality in adults and other high-risk populations, but pneumonia may

also complicate varicella in young children. Respiratory symptoms, which may include cough, dyspnea, cyanosis, pleuritic chest pain, and hemoptysis, usually begin within 1–6 days after the onset of the rash. Smoking has been described as a risk factor for severe pneumonia complicating varicella. The frequency of varicella pneumonia may be greater in the parturient and may lead to premature termination of pregnancy.

Prognosis.

Primary varicella has a mortality rate of 2–3 per 100,000 cases with the lowest case fatality rates among children 1–4 years and 5–9 years (approximately 1 death per 100,000 cases). Compared with these age groups, infants have a 4 times greater risk of dying and adults have a 25 times greater high risk of dying. Approximately 100 deaths occurred in the United States annually before the introduction of the VZV vaccine; the most common complications among people who died from varicella were pneumonia, CNS complications, secondary infections, and hemorrhagic conditions. The mortality rate of untreated primary infection in immunocompromised children is 7–14% and may approach 50% in adults. Varicella morbidity has declined in recent years as vaccine coverage has improved. It is expected that when data are available, a decline in mortality will also be apparent.

Neuritis with herpes zoster should be managed with appropriate analgesics. Postherpetic neuralgia can be a severe problem in adults and may persist for months, requiring care by a specialist in pain management.

Prevention.

VZV transmission is difficult to prevent because the infection is contagious for 24–48?hr before the rash appears. Infection control practices, including caring for infected patients in isolation rooms with filtered air systems, are essential. All health care workers should have documented VZV immunization or immunity. Susceptible health care workers who have had a close exposure to VZV should not care for high-risk patients during the incubation period.

VACCINE.

Varicella is a vaccine-preventable disease. Live virus vaccine is recommended for routine administration in children at 12–18 mo of age. Older children, adolescents and adults without a history of VZV infection should also be immunized. Children 12 mo to 12 yr receive a single vaccine dose; adolescents and adults require 2 vaccine doses, a minimum of 4 wk apart. Live virus vaccine is contraindicated in children with cell-mediated immune deficiencies, although the vaccine may be administered to children with acute lymphoblastic leukemia who are in remission and who meet enrollment criteria under a research protocol, and the vaccine may also be considered for HIV-infected children with CD4% greater than 25%. Both these groups receive 2 doses of vaccine, 3 months apart. Administration of varicella vaccine within 4 wk of MMR vaccine has been associated with a higher risk of breakthrough disease; therefore, it is recommended that the vaccines either be administered simultaneously at different sites or be given at least 4 weeks apart. Vaccine virus establishes latent infection; however, the risk of developing subsequent herpes zoster is lower after vaccine than after natural VZV infection among immunocompromised children. Post-licensure data also suggest the same trend in healthy vaccinees. Post-licensure effectiveness

studies and ongoing studies of the persistence of immunity after vaccination, however, may ultimately demonstrate a need for children to receive a booster dose of vaccine.

POSTEXPOSURE PROPHYLAXIS.

Varicella-zoster immune globulin (VZIG) postexposure prophylaxis is recommended for immunocompromised children, pregnant women, and newborns exposed to maternal varicella. VZIG is distributed by FFF Enterprises, California. The dosage is 1 vial (125 units) for each 10?kg increment (maximum: 625 units) given intramuscularly as soon as possible but within 96?hr after exposure.

Newborns whose mothers develop varicella 5 days before to 2 days after delivery should receive one vial of VZIG. Adults should be tested for VZV IgG antibodies before VZIG administration because many adults with no clinical history of varicella are immune. VZIG prophylaxis may ameliorate disease but does not eliminate the possibility of progressive disease; patients should be monitored and treated with acyclovir if necessary. Immunocompromised patients who have received high-dose intravenous immune globulin (100–400?mg/kg) for other indications within 2–3 wk before the exposure can be expected to have serum antibodies to VZV.

Close contact between a susceptible high-risk patient and a patient with herpes zoster is also an indication for VZIG prophylaxis. Passive antibody administration or treatment does not reduce the risk of herpes zoster or alter the clinical course of varicella or herpes zoster when given after the onset of symptoms.

Vaccine given to normal children within 3–5 days exposure is effective in preventing or modifying varicella, especially in a household setting where exposure is very likely to result in infection. Varicella vaccine is now recommended for postexposure use, for outbreak control. Oral acyclovir administered late in the incubation period may modify subsequent varicella in the normal child. However, its use in this manner is not recommended until it can be further evaluated.

Chapter 233 - Epstein-Barr Virus

Hal B. Jenson

Infectious mononucleosis is the best-known clinical syndrome caused by Epstein-Barr virus (EBV). It is characterized by systemic somatic complaints consisting primarily of fatigue, malaise, fever, sore throat, and generalized lymphadenopathy. Originally described as **glandular fever**, it derives its name from the mononuclear lymphocytosis with atypical-appearing lymphocytes that accompany the illness. Other infections may cause infectious mononucleosis-like illnesses.

Etiology.

EBV, a member of the ?-herpesviruses, causes more than 90% of infectious mononucleosis cases. As many as 5–10% of infectious mononucleosis-like illnesses are caused by primary infection with cytomegalovirus, *Toxoplasma gondii*, adenovirus, viral hepatitis, HIV, and possibly rubella virus. In the majority of EBV-negative infectious mononucleosis-like illnesses, the exact cause remains unknown.

Epidemiology.

The epidemiology of infectious mononucleosis is related to the epidemiology and age of acquisition of EBV infection. EBV infects >95% of the world's population. It is transmitted in oral secretions by close contact such as kissing or exchange of saliva from child to child, such as occurs between children in out-of-home child care. Nonintimate contact, environmental sources, or fomites do not contribute to spread of EBV.

EBV is shed in oral secretions for >6 mo after acute infection and then intermittently for life. As many as 20–30% of healthy EBV-infected persons excrete virus at any particular time. Immunosuppression permits reactivation of latent EBV; 60–90% of EBV-infected immunosuppressed patients shed the virus. EBV is also found in the genital tract of women and may be spread by sexual contact.

Infection with EBV in developing countries and among socioeconomically disadvantaged populations of developed countries usually occurs during infancy and early childhood. In central Africa, almost all children are infected by 3 yr of age. Primary infection with EBV during childhood is usually inapparent or indistinguishable from other childhood infections; the clinical syndrome of infectious mononucleosis is practically unknown in undeveloped regions of the world. Among more affluent populations in industrialized countries, infection during childhood is still most common, but approximately one third of cases occur during adolescence and young adulthood. Primary EBV infection in adolescents and adults is manifest in >50% of cases by the classic triad of fatigue, pharyngitis, and generalized lymphadenopathy, which constitute the major clinical manifestations of infectious mononucleosis. This syndrome may be seen at all ages but is rarely apparent in children <4 yr of age, when most EBV infections are asymptomatic, or in adults >40 yr of age, when most individuals have already been infected by EBV. The true incidence of the syndrome of infectious mononucleosis is unknown but is estimated to occur in 20–70/100,000 persons/yr; in young adults, the incidence increases to about 1/1,000 persons/yr. The prevalence of serologic evidence of past EBV infection increases with age; almost all adults in the United States are seropositive.

Pathogenesis.

After acquisition in the oral cavity, EBV initially infects oral epithelial cells; this may contribute to the symptoms of pharyngitis. After intracellular viral replication and cell lysis with release of new virions, virus spreads to contiguous structures such as the salivary glands, with eventual viremia and infection of B lymphocytes in the peripheral blood and the entire lymphoreticular system, including the liver and spleen. The atypical lymphocytes that are characteristic of infectious mononucleosis are $CD8^+$ T lymphocytes, which exhibit both suppressor and cytotoxic functions that develop in response to the infected B lymphocytes. This relative as well as absolute increase in $CD8^+$ lymphocytes results in a transient reversal of the normal 2rc1 $CD4^+$/$CD8^+$ (helper-suppressor) T-lymphocyte ratio. Many of the clinical manifestations of infectious mononucleosis may result, at least in part, from the host immune response, which is effective in reducing the number of EBV-infected B lymphocytes to less than 1 per 10^6 of circulating B lymphocytes.

Epithelial cells of the uterine cervix may become infected by sexual transmission of the virus, although neither local symptoms nor infectious mononucleosis have been described after sexual transmission.

EBV, like the other herpesviruses, establishes lifelong latent infection after the primary illness. The latent virus is carried in oropharyngeal epithelial cells and systemic B lymphocytes as multiple episomes in the nucleus. The viral episomes replicate with cell division and are distributed to both daughter cells. Viral integration into the cell genome is not typical. Only a few viral proteins, including the EBV-determined antigens (EBNA), are produced during latency. These proteins are important in maintaining the viral episome during the latent state. Progression to viral replication begins with production of EBV early antigens (EA), proceeds to viral DNA replication, is followed by production of viral capsid antigen (VCA), and culminates in cell death and release of mature virions. Reactivation with viral replication occurs at a low rate in populations of latently infected cells and is responsible for intermittent

viral shedding in oropharyngeal secretions of infected individuals. Reactivation is apparently asymptomatic and not recognized to be accompanied by distinctive clinical symptoms.

ONCOGENESIS.

EBV was the first human virus to be associated with malignancy and, therefore, was the first virus to be identified as a human tumor virus. EBV infection may result in a spectrum of proliferative disorders ranging from self-limited, usually benign disease such as infectious mononucleosis to aggressive, nonmalignant proliferations such as the virus-associated hemophagocytic syndrome to lymphoid and epithelial cell malignancies. Benign EBV-associated proliferations include oral hairy leukoplakia, primarily in adults with AIDS, and lymphoid interstitial pneumonitis, primarily in children with AIDS. Malignant EBV-associated proliferations include nasopharyngeal carcinoma, Burkitt lymphoma, Hodgkin disease, lymphoproliferative disorders, and leiomyosarcoma in immunodeficient states, including AIDS.

Nasopharyngeal carcinoma occurs worldwide but is 10 times more common in persons in southern China, where it is the most common malignant tumor among adult men. It is also common among whites in North Africa and Inuits in North America. Patients usually present with cervical lymphadenopathy and eustachian tube blockage and nasal obstruction with epistaxis. All malignant cells of undifferentiated nasopharyngeal carcinoma contain a high copy number of EBV episomes. Persons with undifferentiated and partially differentiated, nonkeratinizing nasopharyngeal carcinomas have elevated EBV antibody titers that are both diagnostic and prognostic. High levels of immunoglobulin (Ig) A antibody to EA and VCA may be detected in asymptomatic individuals and can be used to follow response to tumor therapy (Table 233–1). Cells of well-differentiated, keratinizing nasopharyngeal carcinoma contain a low or zero copy number of EBV genomes; these persons have EBV serologic patterns similar to those of the general population.

CT and MRI images are helpful in both identifying and defining masses in the head and neck. The diagnosis is established by biopsy of the mass or of a suspicious cervical lymph node. Surgery is important for staging and diagnosis. Radiation therapy is effective for control of the primary tumor and regional nodal metastases. Chemotherapy with 5-fluorouracil, cisplatin, and methotrexate is effective but not always curative. The prognosis is good if the tumor is localized.

Endemic (African) Burkitt lymphoma, often found in the jaw, is the most common childhood cancer in equatorial East Africa and New Guinea (Chapter 488.2). The median age at onset is 5 yr. These regions are holoendemic for *Plasmodium falciparum* malaria and have a high rate of EBV infection early in life.

TABLE 233-1 -- **Correlation of Clinical Status and Serologic Responses to EBV Infection**

Clinical Status	Serologic Response					
	Heterophile Antibodies (Qualitative Test)	***EBV-Specific Antibody***				
		IgM-VCA	***IgG-VCA***	***EA-D***	***EA-R***	***EBNA***
Negative reaction	-	<1:8[*]	<1:10[*]	<1:10[*]	<1:10[*]	<1:2.5[*]
Susceptible	-	-	-	-	-[†]	-
Acute primary infection: infectious mononucleosis	+	1:32 to 1:256	1:160 to 1:640	1:40 to 1:160	-[†]	- to 1:2.5
Recent primary infection: infectious mononucleosis	+/-	- to 1:32	1:320 to 1:1,280	1:40 to 1:160	-[†]	1:5 to 1:10
Remote infection	-	-	1:40 to 1:160	-[‡]	- to 1:40	1:10 to 1:40
Reactivation: immunosuppressed or immunocompromised	-	-	1:320 to 1:1,280	-[‡]	1:80 to 1:320	- to 1:160
Burkitt lymphoma	-	-	1:320 to 1:1,280	-[‡]	1:80 to 1:320	1:10 to 1:80
Nasopharyngeal carcinoma	-	-	1:320 to 1:1,280	1:40 to 1:160	-[§]	1:20 to 1:160

The data were obtained from numerous studies. Individual responses outside the characteristic range may occur.

EBV = Epstein-Barr virus; - = negative; + = positive; IgM = immunoglobulin M; IgG = immunoglobulin G; VCA = viral capsid antigen; EA-D = diffuse staining component of EA; EA-R = cytoplasmic restricted component of early antigen; EBNA = EBV-determined nuclear antigens.

**Or the lowest test dilution.*
†In young children and adults with asymptomatic seroconversion, the anti–early antigen response may be mainly to the EA-R component.
‡A minority of individuals will have the anti–early antigen response mainly to the EA-D component.
§A minority of individuals will have the anti–early antigen response mainly to the EA-R component.

The constant malarial exposure acts as a B-lymphocyte mitogen that contributes to

the polyclonal B-lymphocyte proliferation with EBV infection. It also impairs the T-lymphocyte control of EBV-infected B lymphocytes. Approximately 98% of cases of endemic Burkitt lymphoma contain the EBV genome compared with only 20% of nonendemic (sporadic or American) Burkitt lymphoma cases. Individuals with Burkitt lymphoma have unusually and characteristically high levels of antibody to VCA and EA that correlate with the risk of developing tumor (see Table 233–1).

All cases of Burkitt lymphoma, including those that are EBV negative, are monoclonal and demonstrate chromosomal translocation of the c-*myc* proto-oncogene to the constant region of the immunoglobulin heavy-chain locus, t(8;14), to the kappa constant light-chain locus, t(2;8), or to the lambda constant light-chain locus, t(8;22). This results in the deregulation and constitutive transcription of the c-*myc* gene with overproduction of a normal c-*myc* product that autosuppresses c-*myc* production on the untranslocated chromosome.

The incidence of **Hodgkin disease** peaks in childhood in developing countries and in young adulthood in developed countries. Levels of EBV antibodies are consistently elevated preceding development of Hodgkin disease; only a small minority of patients are seronegative for EBV. Infection with EBV appears to increase the risk of Hodgkin disease by a factor of 2 to 4. EBV is associated with more than one half of cases of mixed cellularity Hodgkin disease and approximately one fourth of cases of the nodular sclerosing subtype and is rarely associated with lymphocyte-predominant Hodgkin disease. Immunohistochemical studies have localized EBV to the Reed-Sternberg cells and their variants, the pathognomonic malignant cells of Hodgkin disease.

Failure to control EBV infection may result from host immunologic deficits. The prototype is the **X-linked lymphoproliferative syndrome (Duncan syndrome)**, an X chromosome–linked recessive disorder of the immune system associated with severe, persistent, and sometimes fatal EBV infection (Chapter 114.7). Approximately two thirds of these male patients die of disseminated and fulminating lymphoproliferation involving multiple organs at the time of primary EBV infection. Surviving patients acquire hypogammaglobulinemia, B-cell lymphoma, or both. Most patients die within 10 yr.

A number of other congenital and acquired immunodeficiency syndromes are associated with an increased incidence of EBV-associated B-lymphocyte lymphoma, particularly central nervous system lymphoma and leiomyosarcoma. The incidence of lymphoproliferative syndromes parallels the degree of immunosuppression. A decline in T-cell function evidently permits EBV to escape from immune surveillance. Congenital immunodeficiencies predisposing to EBV-associated lymphoproliferations include the X-linked lymphoproliferative syndrome, common- variable immunodeficiency, ataxia-telangiectasia, Wiskott-Aldrich syndrome, and Chediak-Higashi syndrome. Individuals with acquired immunodeficiencies resulting from anticancer chemotherapy, immunosuppression after solid organ or bone marrow transplantation, or HIV infection have a significantly increased risk of EBV-associated lymphoproliferations. The lymphomas may be focal or diffuse, and they are usually histologically polyclonal but may become monoclonal. Their growth is not reversed on cessation of immunosuppression.

EBV has been credibly linked to leiomyosarcomas in HIV-infected patients and transplant patients, primary central nervous system lymphoma, and carcinoma of the salivary glands. Other tumors putatively associated with EBV include some T-lymphocyte lymphomas (including lethal midline), angioimmunoblastic lymphadenopathy-like lymphoma, thymomas and thymic carcinomas derived from thymic epithelial cells, supraglottic laryngeal carcinomas, lymphoepithelial tumors of the respiratory tract and gastrointestinal tract, and gastric adenocarcinoma. The precise contribution of EBV to these various malignancies is not well defined.

Clinical Manifestations.

The incubation period of infectious mononucleosis in adolescents is 30–50 days. In children, it may be shorter. The majority of cases of primary EBV infection in infants and young children are clinically silent. In older patients, the onset of illness is usually insidious and vague. Patients may complain of malaise, fatigue, fever, headache, sore throat, nausea, abdominal pain, and myalgia. This prodromal period may last 1–2 wk. The complaints of sore throat and fever gradually increase until patients seek medical care. Splenic enlargement may be rapid enough to cause left upper quadrant abdominal discomfort and tenderness, which may be the presenting complaint.

The physical examination is characterized by generalized lymphadenopathy (90% of cases), splenomegaly (50% of cases), and hepatomegaly (10% of cases). Lymphadenopathy occurs most commonly in the anterior and posterior cervical nodes and the submandibular lymph nodes and less commonly in the axillary and inguinal lymph nodes. Epitrochlear lymphadenopathy is particularly suggestive of infectious mononucleosis. Symptomatic hepatitis or jaundice is uncommon. Splenomegaly to 2–3?cm below the costal margin is typical; massive enlargement is uncommon.

The sore throat is often accompanied by moderate to severe pharyngitis with marked tonsillar enlargement, occasionally with exudates (Fig. 233–1). Petechiae at the junction of the hard and soft palate are frequently seen. The pharyngitis resembles that caused by streptococcal infection. Other clinical findings may include rashes and edema of the eyelids. Rashes are usually maculopapular and have been reported in 3–15% of patients. Up to 80% of patients with infectious mononucleosis experience **"ampicillin rash"** if treated with ampicillin or amoxicillin. This vasculitic rash is probably immune-mediated and resolves without specific treatment.

Diagnosis.

The diagnosis of infectious mononucleosis implies primary EBV infection. A presumptive diagnosis may be made by the presence of typical clinical symptoms with atypical lymphocytosis in the peripheral blood. The diagnosis is confirmed by serologic testing.

DIFFERENTIAL DIAGNOSIS.

Infectious mononucleosis-like illnesses may be caused by primary infection with cytomegalovirus, *T. gondii*, adenovirus, viral hepatitis, HIV, or possibly rubella virus. Cytomegalovirus infection is a particularly common cause in adults. Streptococcal pharyngitis may cause sore throat and cervical lymphadenopathy indistinguishable from that of infectious mononucleosis but is not associated with

hepatosplenomegaly. Approximately 5% of cases of EBV-associated infectious mononucleosis have positive throat cultures for group A ß-hemolytic streptococci; this represents pharyngeal streptococcal carriage. Failure of a patient with streptococcal pharyngitis to improve within 48–72?hr should evoke suspicion of infectious mononucleosis. The most serious problem in the diagnosis of acute illness arises in the occasional patient with extremely high or low white blood cell counts, moderate thrombocytopenia, and even hemolytic anemia. In these patients, bone marrow examination

Figure 233-1 Tonsillitis with membrane formation in infectious mononucleosis. (Courtesy of Alex J. Steigman, MD)

---

and hematologic consultation are warranted to exclude the possibility of leukemia.

ROUTINE LABORATORY TESTS.

In >90% of cases there is leukocytosis of 10,000–20,000 cells/mm^3 , of which at least two thirds are lymphocytes; atypical lymphocytes usually account for 20–40% of the total number. The atypical cells are mature T lymphocytes that have been antigenically activated. Compared with regular lymphocytes microscopically, atypical lymphocytes are larger overall, with larger, eccentrically placed indented and folded nuclei with a lower nuclear-to-cytoplasm ratio. Although atypical lymphocytosis may be seen with many of the infections usually causing lymphocytosis, the highest degree of atypical lymphocytes is classically seen with EBV infection. Other syndromes associated with atypical lymphocytosis include acquired cytomegalovirus infection (in contrast to congenital cytomegalovirus infection), toxoplasmosis, viral hepatitis, rubella, roseola, mumps, tuberculosis, typhoid, *Mycoplasma* infection, and malaria, as well as some drug reactions. Mild thrombocytopenia to 50,000–200,000 platelets/mm^3 occurs in >50% of patients, but only rarely are values low enough to cause purpura. Mild elevation of hepatic transaminases occurs in approximately 50% of uncomplicated cases but is usually asymptomatic without jaundice.

HETEROPHILE ANTIBODY TEST.

Heterophile antibodies agglutinate cells from species different from those in the source serum. The transient heterophile antibodies seen in infectious mononucleosis, also known as Paul-Bunnell antibodies, are IgM antibodies detected by the Paul-Bunnell-Davidsohn test for sheep red cell agglutination. The heterophile antibodies of infectious mononucleosis agglutinate sheep or, for greater sensitivity, horse red cells but not guinea pig kidney cells. This adsorption property differentiates this response from the heterophile response found in patients with serum sickness, rheumatic diseases, and some normal individuals. Titers greater than 1:28 or 1:40 (depending on the dilution system used) after absorption with guinea pig cells are considered positive.

The sheep red cell agglutination test is likely to be positive for several months after infectious mononucleosis; the horse red cell agglutination test may be positive for as long as 2 yr. The most widely used method is the qualitative rapid slide test using horse erythrocytes. It detects heterophile antibody in 90% of cases of EBV-associated infectious mononucleosis in older children and adults but in only up to 50% of cases in children <4 yr of age because they typically develop a lower titer. From 5–10% of cases of infectious mononucleosis are not caused by EBV and are not uniformly associated with a heterophile antibody response. The false-positive rate is <10%, usually resulting from erroneous interpretation. If the heterophile test is negative and an EBV infection is suspected, EBV-specific antibody testing is indicated.

SPECIFIC EBV ANTIBODIES.

EBV-specific antibody testing is useful to confirm acute EBV infection, especially in heterophile-negative cases, or to confirm past infection and determine susceptibility to future infection. Several distinct EBV antigen systems have been characterized for diagnostic purposes (Fig. 233–2 and see Table 233–1). The EBNA, EA, and VCA antigen systems are most useful for diagnostic purposes. The acute phase of infectious mononucleosis is characterized by rapid IgM and IgG antibody responses to VCA in all cases and an IgG response to EA in most cases. The IgM response to VCA is transient but can be detected for at least 4 wk and occasionally up to 3 mo. The laboratory must take steps to remove rheumatoid factor, which may cause a false-positive IgM VCA result. The IgG response to VCA usually peaks late in the acute phase, declines slightly over the next several weeks to months, and then persists at a relatively stable level for life.

Anti-EA antibodies are usually detectable for several months but may persist or be detected intermittently at low levels for many years. Antibodies to the diffuse-staining component of EA, EA-D, are found transiently in 80% of patients during the acute phase of infectious mononucleosis and reach high titers in patients with nasopharyngeal carcinoma. Antibodies to the cytoplasmic-restricted component of EA, EA-R, emerge transiently in the convalescence from infectious mononucleosis and often attain high titers in patients with EBV-associated Burkitt lymphoma, which in the terminal stage of the disease may be exceeded by antibodies to EA-D. High levels of antibodies to EA-D or EA-R may be found also in immunocompromised patients with persistent EBV infections and active EBV replication. Anti-EBNA antibodies are the last to develop in infectious mononucleosis and gradually appear 3–4 mo after the onset of illness and remain at low levels for life. Absence of anti-EBNA when other antibodies are present implies recent infection, whereas the presence of anti-EBNA implies infection occurring more than 3–4 mo previously. The wide range of individual antibody responses and the various laboratory methods used can occasionally make interpretation of an antibody profile difficult. The detection of IgM antibody to VCA is the most valuable and specific serologic test for the diagnosis of acute EBV infection and is generally sufficient to confirm the diagnosis.

Treatment.

There is no specific treatment for infectious mononucleosis. Therapy with high doses of acyclovir, with or without

Figure 233-2 Schematic representation of the development of antibodies to various Epstein-Barr

virus antigens in patients with infectious mononucleosis. The titers are geometric mean values expressed as reciprocals of the serum dilution. The immunoglobulin M (IgM) response to viral capsid antigen (VCA) is divided because of the significant differences noted according to age of the patient. IgG, immunoglobulin G. (Reprinted with permission from Jenson HB, Ench Y: Epstein-Barr virus. In Rose NR, Hamilton RG, Detrick B [editors]: *Manual of Clinical Laboratory Immunology*, 6th ed. Washington, DC, American Society for Microbiology, 2002.)

corticosteroids, decreases viral replication and oropharyngeal shedding during the period of administration but does not reduce the severity or duration of symptoms or alter the eventual outcome. Rest and symptomatic therapy are the mainstays of management. Bed rest is necessary only when the patient has debilitating fatigue. As soon as there is definite symptomatic improvement, the patient should be allowed to begin resuming normal activities. Because blunt abdominal trauma may predispose patients to splenic rupture, it is customary and prudent to advise against participation in contact sports and strenuous athletic activities during the first 2–3 wk of illness or while splenomegaly is present.

Short courses of corticosteroids (less than 2 wk) may be helpful for complications of infectious mononucleosis, but this use has not been evaluated critically. Some appropriate indications include incipient airway obstruction, thrombocytopenia with hemorrhaging, autoimmune hemolytic anemia, and seizures and meningitis. A recommended dosage is prednisone, 1?mg/kg/ 24?hr (maximum: 60?mg/24?hr) or equivalent, for 7 days and tapered over another 7 days. There are no controlled data to show efficacy of corticosteroids in any of these conditions. In view of the potential and unknown hazards of immunosuppression for a virus infection with oncogenic complications, corticosteroids should not be used in uncomplicated cases of infectious mononucleosis.

Complications.

Very few patients with infectious mononucleosis experience complications. The most feared complication is subcapsular splenic hemorrhage or splenic rupture, which occurs most frequently during the 2nd week of the disease at a rate of <0.5% of cases in adults; the rate in children is unknown but is probably much lower. Rupture is commonly related to trauma, which often may be mild, and is rarely fatal. Swelling of the tonsils and oropharyngeal lymphoid tissue may be substantial and cause airway obstruction that is manifest by stridor and interference with breathing. Airway impairment with progressive symptoms occurs in <5% of cases and is one of the most common indications for hospitalization with infectious mononucleosis. It may be treated by administration of head-of-bed elevation, intravenous hydration, humidified air, and systemic corticosteroids. Respiratory distress with incipient or actual airway occlusion should be managed by tonsilloadenoidectomy followed by endotracheal intubation for 12–24?hr in an intensive care setting.

Many uncommon and unusual neurologic conditions have been reported to be associated with EBV infectious mononucleosis. Headache is present in about half of cases, with severe neurologic manifestations, such as seizures and ataxia, in 1–5% of cases. Perceptual distortions of sizes, shapes, and spatial relationships, known as the **Alice in Wonderland syndrome (metamorphopsia)**, may be a presenting symptom. There may be meningitis with nuchal rigidity and mononuclear cells in the cerebrospinal fluid, facial nerve palsy, transverse myelitis, and encephalitis.

Guillain-Barré syndrome or Reye syndrome may follow acute illness. Hemolytic anemia, often with a positive Coombs test and with cold agglutinins specific for red cell antigen i, occurs in 3% of cases. The onset is typically in the first 2 wk of illness and lasts for <1 mo. Aplastic anemia is a rare complication that usually presents 3–4 wk after the onset of illness, usually with recovery in 4–8 days but some cases do require bone marrow transplantation. Mild thrombocytopenia and neutropenia are common, but severe thrombocytopenia (<20,000 platelets/µL) or severe neutropenia (<1,000 neutrophils/µL) are rare. Myocarditis or interstitial pneumonia may occur, both resolving in 3–4 wk. Other rare complications include pancreatitis, parotitis, and orchitis.

Prognosis.

The prognosis for complete recovery is excellent if no complications ensue during the acute illness. The major symptoms typically last 2–4 wk, followed by gradual recovery. Second attacks of infectious mononucleosis caused by EBV have not been documented. Fatigue, malaise, and some disability that may wax and wane for several weeks to a few months are common complaints even in otherwise unremarkable cases. Occasional persistence of fatigue for a few years after infectious mononucleosis is well recognized. At present, there is no convincing evidence linking EBV infection or EBV reactivation to chronic fatigue syndrome (Chapter 111).

Chapter 234 - Cytomegalovirus

Sergio Stagno

Human cytomegalovirus (CMV) is a member of the Herpesviridae family and is widely distributed. Most CMV infections are inapparent, but the virus can cause a variety of clinical illnesses that range in severity from mild to fatal. CMV is the most common cause of congenital infection, which occasionally causes the syndrome of **cytomegalic inclusion disease** (hepatosplenomegaly, jaundice, petechia, purpura, and microcephaly). In immunocompetent adults, the infection is occasionally characterized by a mononucleosis-like syndrome. In immunosuppressed individuals, including transplant recipients and patients with AIDS, CMV pneumonitis, retinitis, and gastrointestinal disease are common and can be fatal.

Primary infection occurs in a seronegative, susceptible host. Recurrent infection represents reactivation of latent infection or reinfection of a seropositive immune host. Disease may result from primary or recurrent CMV infection, but the former is a more common cause of severe disease.

Etiology.

CMV is the largest of the herpesviruses, and has a diameter of 200?nm with a double-stranded DNA viral genome of 240?kb in a 64-nm core enclosed by an icosahedral capsid composed of 162 capsomers. The core is assembled in the nucleus of the host cells. The capsid is surrounded by a poorly defined amorphous tegument, which is itself surrounded by a loosely applied, lipid-containing envelope. The envelope is acquired during the budding process through the nuclear membrane into a cytoplasmic vacuole, which contains the protein components of the envelope. Mature viruses exit the cells by reverse pinocytosis. Routine serologic tests do not define specific serotypes. In contrast, restriction endonuclease analysis of CMV DNA shows that, although all known human strains are genetically homologous, none are identical unless obtained from epidemiologically related cases.

Epidemiology.

Seroepidemiologic surveys demonstrate CMV infection in every population examined worldwide. The prevalence of infection, which increases with age, is higher in developing countries and among lower socioeconomic strata of the more developed nations.

Transmission sources of CMV include saliva, breast milk, cervical and vaginal secretions, urine, semen, stools, blood, and tissue or organ transplants. The spread of CMV requires very close or intimate contact because it is very labile. Transmission occurs by direct person-to-person contact, but indirect transmission is possible via contaminated fomites.

The incidence of congenital CMV infection ranges from 0.2 to 2.4% of all live births, with the higher rates among populations with a lower economic standard of living. The risk for fetal infection is greatest with maternal primary CMV infection (30%) and much less likely with recurrent infection (<1%). In the United States, from 1 to 4% of pregnant women acquire primary CMV infection, with as many as 8,000 newborns with neurodevelopmental sequelae associated with congenital CMV infection.

Perinatal transmission is common, accounting for an incidence of 10–60% through the first 6 mo of life. The most important perinatal sources of virus are genital tract secretions at delivery and breast milk. Among CMV-seropositive mothers, virus is detectable in breast milk in 96%, with postnatal transmission occurring in approximately 38% of infants, resulting in symptomatic infection in nearly one half of preterm infants. Infected infants excrete virus for years in saliva and urine.

After the first year of life, the prevalence of infection is dependent on group activities, with childcare centers contributing to rapid spread of CMV among children. Infection rates of 50–80% during childhood are common. For children who are not exposed to other toddlers, the rate of infection increases very slowly throughout the first decade of life. A second peak occurs in adolescence as a result of sexual transmission. Seronegative childcare workers and parents of young children shedding CMV have a 10–20% annual risk of acquiring CMV, which contrasts with 1–3% per year for the general population.

CMV infection may be transmitted in transplanted organs (e.g., kidney, heart, and bone marrow). Following transplantation, many patients excrete CMV as a result of infection acquired from the donor organ or from reactivation of latent infection caused by immunosuppression. Seronegative transplant recipients of organs from seropositive donors are at greatest risk for severe disease.

Health care providers are not at increased risk for acquiring CMV infection from patients. Nosocomial infection is a hazard of transfusion of blood and blood products. In a population with a 50% prevalence of CMV infection, the risk has been estimated at 2.7% per unit of whole blood. Leukocyte transfusions pose a much greater risk. Infection is usually asymptomatic, but even in well children and adults there is a risk of disease if the recipient is seronegative and receives multiple units. Immunocompromised patients and seronegative premature infants have a much higher (10–30%) risk of disease.

Pathogenesis.

Cytomegalic cells contain large intranuclear inclusions and smaller intracytoplasmic inclusions, and are pathognomonic for CMV infection. The virus induces focal mononuclear cell infiltrates, which may be present with or without cytomegalic cells. The virus may induce focal necrosis in the brain and liver, which may be extensive and accompanied by granulomatous change with calcifications. The lung, liver, kidney, gastrointestinal tract, and salivary and other exocrine glands are the most commonly affected organs, although the virus has been found in most cell types. The extent of abnormal organ function and the quantity of virus that can be recovered from infected organs are not related to the number of cytomegalic inclusion–bearing cells, which may be few or absent in each organ section examined.

Clinical Manifestations.

The signs and symptoms of CMV infection vary with age, route of transmission, and immunocompetence of the patient. The infection is subclinical in most patients. In infants and young children, primary CMV infection occasionally causes pneumonitis, hepatomegaly, hepatitis, and petechial rashes. In older children, adolescents, and adults, CMV may cause mononucleosis-like syndrome characterized by fatigue, malaise, myalgia, headache, fever, hepatosplenomegaly, elevated liver enzymes, and atypical lymphocytosis. The course of CMV mononucleosis is generally mild, lasting 2–3 wk. Occasionally clinical presentations may include persistent fever, overt hepatitis, or a morbilliform rash. Recurrent infections are asymptomatic in the immunocompetent host.

IMMUNOCOMPROMISED PERSONS.

The risk of CMV disease is increased in immunocompromised persons, with both primary and recurrent infections (Chapter 164). Illness with a primary infection includes pneumonitis (most common), hepatitis, chorioretinitis, gastrointestinal disease, or fever with leukopenia as isolated entities or as manifestations of generalized disease, which may be fatal. The risk is greatest in bone marrow transplant recipients and in patients with AIDS. Pneumonia, retinitis, and involvement of the central nervous system and gastrointestinal tract are usually severe and progressive. Submucosal ulcerations can occur anywhere in the gastrointestinal tract and may lead to hemorrhage and perforation. Pancreatitis and cholecystitis may also occur.

CONGENITAL INFECTION.

Symptomatic congenital CMV infection was originally termed cytomegalic inclusion disease. Only 5% of all congenitally infected infants have severe cytomegalic inclusion disease, another 5% have mild involvement, and 90% are born with subclinical, but still chronic, CMV infection. The characteristic signs and symptoms include intrauterine growth retardation, prematurity, hepatosplenomegaly and jaundice, thrombocytopenia and purpura, and microcephaly and intracranial calcifications. Other neurologic problems include chorioretinitis, sensorineural hearing loss, and mild increases in cerebrospinal fluid protein. Symptomatic newborns are usually easy to identify. Most symptomatic congenital infections and

those resulting in sequelae are caused by primary rather than reactivated infections in pregnant women. Re-infection with a different strain of CMV can lead to symptomatic congenital infection. Asymptomatic congenital CMV infection is likely a leading cause of sensorineural hearing loss, which occurs in approximately 7% of infected infants.

PERINATAL INFECTION.

Infections resulting from exposure to CMV in the maternal genital tract at delivery or in breast milk occur despite the presence of maternally derived, passively acquired antibody. Approximately 6–12% of seropositive mothers transmit CMV to their infants by contaminated cervical-vaginal secretions and 50% by breast milk. The majority of infants remain asymptomatic and do not exhibit sequelae. Occasionally, perinatally acquired CMV infection is associated with pneumonitis and sepsis-like syndrome. Premature and ill full-term infants may have neurologic sequelae and psychomotor retardation. However, the risk of hearing loss, chorioretinitis, and microcephaly does not appear to be increased. Premature infants with transfusion-acquired CMV infection have a much greater risk of morbidity.

Diagnosis.

Active CMV infection is best confirmed by virus isolation from urine, saliva, bronchoalveolar washings, breast milk, cervical secretions, buffy coat, and tissues obtained by biopsy. Rapid (24?hr) identification is now routine with the centrifugation-enhanced rapid culture system based on the detection of CMV early antigens using monoclonal antibodies. Several methods are used for rapid quantitative detection of CMV antigens, and quantitative polymerase chain reaction (PCR) assays are also available. The presence of viral shedding and active infection does not distinguish between primary and recurrent

infections. A primary infection is confirmed by seroconversion or the simultaneous detection of immunoglobulin (Ig) M and IgG antibodies with low functional avidity. A simple increase in antibody titers in initially seropositive patients must be interpreted with caution because this is occasionally observed years after primary infection. IgG antibodies persist for life. For the first weeks after primary infection, the functional avidity of IgG class antibodies is very low and rises to a peak in 4–5 mo. IgM antibodies can be demonstrated transiently (4–16 wk) during the acute phase of symptomatic as well as asymptomatic primary infection in adults. IgM antibodies are occasionally found with these assays (0.2–1%) in patients with recurrent infection.

Recurrent infection is defined by the reappearance of viral excretion in a patient known to have been seropositive in the past. The distinction between reactivation of endogenous virus and re-infection with a different strain of CMV requires restriction enzyme analysis of viral DNA or the measurement of antibodies against strain-specific epitopes of CMV, such as glycoprotein H epitopes.

In immunocompromised persons, excretion of CMV, increases in IgG titers, and even the presence of IgM antibodies are common, making the distinction between primary and recurrent infections more difficult. Demonstrating viremia by buffy coat culture or detection of CMV DNA implies active disease and worse prognosis regardless of whether the type of infection is primary, recurrent, or uncertain.

CONGENITAL INFECTION.

The definitive method for diagnosis of congenital CMV infection is virus isolation or PCR, which should be performed at or shortly after birth. Urine and saliva are the best specimens for culture. Infants with congenital CMV infection may excrete CMV in the urine for several years. An IgG antibody test is of little diagnostic value because a positive result also reflects maternal antibodies, although a negative result excludes the diagnosis of congenital CMV infection. Demonstration of stable or rising titers in serial specimens during the first year of life does not help because acquired infection in the first few months of life is common. In general, IgM tests lack sensitivity and specificity and are unreliable for diagnosis of congenital CMV infection. Congenital toxoplasmosis and syphilis must also be considered.

IgM antibody tests and the measurement of CMV-IgG avidity can identify women at high risk of transmitting CMV in utero. Fetal infection can be confirmed by viral isolation from amniotic fluid. The sensitivity of this method is excellent after the 22nd wk of gestation. The detection of viral genome by PCR in amniotic fluid is equally sensitive and specific; quantitative PCR demonstrating 10^5 genome equivalents per mL of amniotic fluid is a predictor of symptomatic congenital infection.

Treatment.

There are limited options for treatment of CMV infection. Treatment is not indicated for immunocompetent persons, but is recommended for immunocompromised persons, and remains controversial for infants with symptomatic congenital infection.

IMMUNOCOMPROMISED PERSONS.

Ganciclovir combined with immune globulin, either standard intravenous immunoglobulin (IVIG) or hyperimmune CMV IVIG, has been used to treat life-threatening CMV infections in immunocompromised hosts (e.g., bone marrow, heart, and kidney transplant recipients and patients with AIDS). Two published regimens are: ganciclovir (7.5?mg/kg/24?hr divided q 8?hr IV for 14 days) with CMV IVIG (400?mg/kg on days 1, 2, and 7, and 200?mg/kg on day 14); and ganciclovir (7.5?mg/kg/24?hr divided q 8?hr IV for 20 days with IVIG 500?mg/kg every other day for 10 doses).

CMV retinitis and gastrointestinal disease appear to be clinically responsive to therapy but, like viral excretion, often recur on cessation. Toxicity with ganciclovir is frequent and often severe and includes neutropenia, thrombocytopenia, liver dysfunction, reduction in spermatogenesis, and gastrointestinal and renal abnormalities. Foscarnet is an alternative antiviral agent, although there is limited information on its use in children. CMV prophylaxis with ganciclovir or acyclovir reduces the risk of morbidity in solid organ transplantation. Prophylactic treatment with valacyclovir in adults (2?g q 6?hr PO for 90 days) is a safe and effective

regimen to prevent CMV disease after renal transplantation.

CONGENITAL INFECTION.

A randomized controlled Phase III study with ganciclovir (6?mg/kg/dose q 12?hr IV for the first 6 wk of life) concluded that treatment both prevents hearing deterioration and improves or maintains normal hearing function at 6 mo of age, and may prevent hearing deterioration at 1 yr of age or older. Drug-related toxicity was common with 63% of ganciclovir-treated patients developing significant neutropenia, compared with 21% in the untreated group. The logistic obstacles of intravenous therapy for the first 6 wk of life, limited benefit, and adverse effects have limited enthusiasm for this regimen.

Prognosis.

Patients with CMV mononucleosis usually recover fully, although some have a protracted symptoms. Most immunocompromised patients also recover uneventfully, but many experience severe pneumonitis, with a high fatality rate if hypoxemia develops. CMV infection and disease may be fatal in individuals with increased susceptibility to infections such as patients with AIDS.

CONGENITAL DISEASE.

Nearly 90% of children with symptomatic congenital infection demonstrate central nervous system and hearing defects in later years. Infants with subclinical infection have a much more favorable outlook. Principal concerns are the subsequent development of sensorineural hearing loss (5–10%), chorioretinitis (3–5%), and other less frequent manifestations such as developmental abnormalities, microcephaly, and neurologic deficits.

Prevention.

The use of CMV-free blood products, especially for premature newborns, and, whenever possible, the use of organs from CMV-free donors for transplantation, represent important measures to prevent CMV infection and disease in patients at high risk.

Pregnant women who are CMV seropositive are at low risk of delivering a symptomatic newborn. If possible, pregnant women should have a CMV serologic test, especially if they provide care for young children who are potential CMV excreters. Pregnant women who are CMV seronegative should be counseled regarding good handwashing and other hygienic measures and avoidance of contact with oral secretions of others. Those with suspected recent CMV infection may undergo additional diagnostic evaluations to ascertain in utero transmission and fetal disease.

PASSIVE IMMUNOPROPHYLAXIS.

The use of IVIG or CMV IVIG for prophylaxis of infection in solid organ and bone marrow transplant recipients reduces the risk of symptomatic disease but does not prevent infection. The efficacy of prophylaxis is more striking when the hazard of primary CMV infection is greatest, such as in bone marrow transplantation. There is no consensus for a uniform prophylaxis regimen for CMV infection. Recommended regimens include either IVIG (1,000?mg/ kg) or CMV IVIG (500?mg/kg) given as a single intravenous dose beginning within 72?hr of transplantation and once weekly thereafter until 90–120 days after transplantation.

ACTIVE IMMUNIZATION.

The beneficial role of immunity is substantial, as illustrated by the fact that most severe disease follows primary infection, especially with congenital infection, transfusion-acquired infection, and infection in transplant recipients. Candidates for a CMV vaccine include seronegative women of childbearing age and seronegative transplant recipients. Live, attenuated vaccines based on the Towne strain prototype are immunogenic, but immunity wanes quickly. Vaccine virus does not seem to be transmissible. The vaccine does not

protect renal transplant recipients from CMV infection, but appears to reduce the virulence of primary infection. In a study of vaccine efficacy in normal adult women, the Towne strain vaccine did not provide protection against naturally acquired infection. Other types of vaccines, such as subunit and recombinant vaccines, are being evaluated in early clinical trials. **REFERENCES**

Chapter 235 - Roseola (Human Herpesviruses 6 and 7)

Charles T. Leach

Human herpesvirus 6 (HHV-6) was discovered in 1986, 22 yr after the discovery of the 5th human herpesvirus (Epstein-Barr virus). Six isolates of a new virus were identified in the peripheral blood mononuclear cells (PBMCs) of adult patients with AIDS or lymphoproliferative diseases. In 1990, human herpesvirus 7 (HHV-7) was identified in the peripheral blood mononuclear cells of an HIV-uninfected adult. HHV-6 is the etiologic agent for most cases of roseola infantum (**exanthem subitum**, or **sixth disease**), and also is associated with other diseases in normal and immunocompromised patients. Disease associations for HHV-7 are fewer; only its role in some cases of roseola is well established.

Etiology.

Roseola was first established as a distinct illness at the turn of the 20th century. Until recently, no pathogen could be consistently identified as the agent responsible for roseola. However, it is now clear that primary infection with HHV-6, and less frequently HHV-7, causes the majority of cases of roseola. In studies of children with roseola from Europe and Asia, HHV-6 was responsible for approximately two thirds of cases and HHV-7 caused one fourth of cases. Other viruses (e.g., echovirus 16) probably account for the remainder.

HHV-6 and HHV-7 belong to the ß-herpesvirus subfamily of herpesviruses, which includes human cytomegalovirus (CMV). HHV-6 and HHV-7 share physical and biologic characteristics with other herpesviruses, including a large double-stranded DNA genome, the presence of a nucleocapsid, and the establishment of latency after primary infection. HHV-6 is essentially colinear with HHV-7, and both viruses share much homology with CMV. The principal target cells for HHV-6 and HHV-7 infection in vivo are CD4 T cells; HHV-6 can also infect other cells, including CD8 (suppressor) T cells, natural killer T cells, d? T cells, glial cells, epithelial cells, monocytes, megakaryocytes, and endothelial cells. HHV-6 and HHV-7 are typically cultivated in vitro in mitogen-stimulated human mononuclear cells (isolated from cord blood or peripheral blood) and can be identified by the development of large balloon-like cells accompanied by cell lysis. Two distinct types of HHV-6 (types A and B) exist. Type B causes more than 99% of HHV-6–associated roseola cases.

Latent type A virus can be found in immunodeficient as well as healthy patients and may reactivate in severely ill adult patients. However, it has not been consistently linked with any disease.

Epidemiology.

Primary HHV-6 infection occurs early in life. More than 90% of newborn infants are HHV-6 seropositive, reflecting transplacental transfer of maternal antibodies. By 4–6 mo of age, the prevalence drops significantly (0–60%). By 12 mo of age, 60–90% of children possess antibodies to HHV-6, and by 3–5 yr, 80–100% of children are seropositive. Peak acquisition of primary HHV-6 infection, from 6–15 mo of age, corresponds with peak acquisition of roseola. Less than half of HHV-6 infections in U.S. infants are clinically recognizable as roseola, whereas 80% of Japanese infants with primary HHV-6 infection develop roseola. Primary infection with HHV-7 occurs slightly later than HHV-6 infection, with 45–75% of children infected by 2 yr of age and 90% by 7–10 yr of age.

Roseola can develop in children year-round; some series indicate a higher incidence during spring and fall months. Unlike some of the other childhood exanthems, children with roseola rarely report contact with other affected children, and outbreaks are uncommon. Sex, race, and geography do not play an important role in acquisition of roseola. The incubation period averages 10 days (range of 5–15 days).

Most adults excrete HHV-6 and HHV-7 in saliva and may serve as primary sources for virus transmission to children. Women excrete HHV-6 and HHV-7 in the genital tract at low rates, but sexual transmissibility has not been demonstrated. There is evidence that HHV-6 can be transmitted in utero, although this is a rare occurrence and no malformations have been noted. No congenital HHV-7 infections have been described. HHV-6 has been transmitted to susceptible infant transplant recipients via infected donor bone marrow or solid organ. There is no evidence that infection is spread by breast milk or blood transfusion.

Pathogenesis.

Little is known regarding the pathogenesis of infections associated with HHV-6 and HHV-7, including roseola. Virus is probably acquired from the saliva of healthy persons and enters the host through the oral, nasal, or conjunctival mucosa. Cellular receptors for both viruses have been identified: HHV-6 uses the CD46 receptor (also used by measles virus), and HHV-7 uses the CD4 receptor (also used by HIV-1). Following viral replication at an unknown site, a high level of viremia develops in PBMCs. After acute infection, HHV-6 and HHV-7 establish latency in blood mononuclear cells and possibly in the salivary glands, kidneys, lungs, and central nervous system. Both viruses may evade the immune system through downregulation of the major histocompatibility complex (MHC) type I response. The basis for the unique pattern of rash after resolution of fever in children with roseola has not been established.

HHV-6 can suppress all cellular lineages within the bone marrow, and active HHV-6 infection is associated with bone marrow suppression in bone marrow transplant patients. HHV-6 infection also has significant effects on the immune system, including enhancement of natural killer (NK) T-cell activity, suppression of PBMC proliferation, and induction of a proinflammatory cytokine response.

Clinical Manifestations.

Roseola is the prototypical HHV-6 and HHV-7 infection, although nonspecific infections are common.

ROSEOLA INFANTUM (EXANTHEM SUBITUM).

Roseola is a mild febrile, exanthematous illness occurring almost exclusively during infancy. More than 95% of roseola cases occur in children younger than 3 yr, with a peak at 6–15 mo of age. Transplacental antibodies likely protect most infants until 6 mo of age.

Infants with classic roseola exhibit a unique constellation of findings displayed over a short period of time. Consequently, classic roseola is infrequently confused with other childhood exanthems.

The prodromal period of roseola is usually asymptomatic but may include mild upper respiratory tract signs, among them minimal rhinorrhea, slight pharyngeal inflammation, and mild conjunctival redness. Mild cervical or, less frequently, occipital lymphadenopathy may be noted. Some children may have mild palpebral edema. Physical findings during the prodromal stage have no clear relationship to roseola, and may simply reflect an accompanying respiratory viral infection.

Clinical illness is generally heralded by high temperature, usually ranging from 37.9 to 40℃ (101–106℉), with an average of 39℃ (103℉). Some children may become irritable and anorexic during the febrile stage, but most behave normally despite high temperatures. Seizures may occur in 5–10% of children with roseola during this febrile period. Infrequent complaints include rhinorrhea, sore throat, abdominal pain, vomiting, and diarrhea. In Asian countries, ulcers at the uvulopalatoglossal junction (**Nagayama spots**) are common in infants with roseola.

Fever persists for 3–5 days, and then typically resolves rather abruptly ("crisis"). Occasionally, the fever may gradually diminish over 24–36 hours ("lysis"). A rash appears within 12–24?hr of fever resolution. In many cases, the rash develops during defervescence or within a few hours of fever resolution. The rash of roseola is rose colored, as the name implies, and is fairly distinctive. However, it may be confused with exanthems resulting from rubella, measles, or erythema infectiosum. The roseola rash begins as discrete, small (2–5?mm), slightly raised pink lesions on the trunk and usually spreads to the neck, face, and proximal extremities. The rash is not usually pruritic, and no vesicles or pustules develop. Lesions typically remain discrete but occasionally may become almost confluent. After 1–3 days, the rash fades. Some children experience evanescent rashes that resolve within a few hours.

Subtle differences in clinical presentation have been noted between roseola associated with HHV-7 compared with HHV-6. These include a slightly older age,

lower mean temperature, and shorter duration of fever in HHV-7-associated cases. However, these differences are insufficient to clinically distinguish HHV-6– from HHV-7–associated roseola. There are reports of children experiencing HHV-6–associated roseola followed later by HHV-7–associated roseola.

FEVER IN INFANTS WITHOUT CLASSIC ROSEOLA.

HHV-6 and HHV-7 account for a significant proportion of nonspecific febrile illnesses in infants. Studies among infants presenting to a hospital emergency room indicate that approximately 15% had primary HHV-6 or HHV-7 infection.

CENTRAL NERVOUS SYSTEM INFECTIONS.

Both HHV-6 and HHV-7 are neurotropic and can invade the CNS. Primary HHV-6 infection is responsible for one third of febrile seizures in infants. Most of these children (70–80%) do not subsequently experience a rash. Smaller studies suggest that HHV-7 also is associated with some febrile seizures. HHV-6 and HHV-7 are also associated with rare cases of encephalitis and meningoencephalitis. One large study noted HHV-6 DNA in cerebrospinal fluid from 6% of children and adults with focal encephalitis of unknown cause.

MONONUCLEOSIS-LIKE ILLNESS AND HEPATITIS.

Several heterophile-negative mononucleosis-like infections associated with HHV-6 have been reported in adults. HHV-6 and HHV-7 may rarely cause clinical symptoms of hepatitis. Some infants have developed HHV-6-associated liver failure, and one fatal case of hepatitis was reported in a neonate after maternal transmission of HHV-6.

INFECTIONS IN IMMUNOCOMPROMISED PATIENTS.

Numerous severe and occasionally fatal HHV-6–associated infections (encephalitis and pneumonitis) have occurred in immunocompromised patients, including patients with AIDS or organ transplants. These have occurred predominantly in stem cell transplant recipients and usually reflect reactivated HHV-6 infection. Recent studies suggest that concomitant HHV-6 and HHV-7 infections may augment CMV-associated disease following organ transplantation.

Because HHV-6 shares CD4 cell tropism with HIV, upregulates HIV, and stimulates in vitro replication of HIV, there has been considerable interest in the role of HHV-6 as a cofactor for clinical progression of AIDS. Epidemiologic studies in adults do not support a significant role for HHV-6 as a cofactor, but one small pediatric study does suggest more rapid progression of immune deficiency in HIV/HHV-6 coinfected patients. Further prospective studies are necessary to assess the impact of HHV-6 on HIV-infected children.

OTHER DISEASES POSSIBLY ASSOCIATED WITH HHV-6 OR HHV-7.

Rash illness without fever has been described in a small number of infants with primary HHV-6 infection. Other small studies or case reports have suggested that HHV-6 may be associated with some cases of hemophagocytic syndrome, intussusception, idiopathic thrombocytopenic purpura, recurrent aphthous stomatitis, myocarditis, and disseminated disease. There are conflicting data linking HHV-7 and pityriasis rosea, a benign exanthematous illness. HHV-6, like several other infectious agents, has been linked to multiple sclerosis by some, but not all, investigators.

HHV-6 DNA has been detected in various malignancies, including non-Hodgkin lymphoma, Hodgkin disease, cervical and oral carcinoma, and leukemia. However, no consistent etiologic relationship has been established with any of these cancers.

Diagnosis.

The most important reason for establishing the diagnosis of roseola is to differentiate this generally mild illness from other potentially more serious childhood rash illnesses such as measles. It is also important to identify other, more serious illnesses caused by HHV-6, such as encephalitis and pneumonitis, especially in immunocompromised patients, for timely consideration of antiviral therapy.

The diagnosis of roseola can be established primarily on the basis of age, history, and clinical findings. HHV-6- and HHV-7-associated roseola cases cannot be distinguished solely on clinical grounds. Specific testing for HHV-6 or HHV-7 infection may be performed using laboratory methods, including serology, virus culture, antigen detection, and polymerase chain reaction (PCR).

HHV-6 serologic testing is available from many commercial laboratories; few offer HHV-7 serology. An HHV-6 immunoglobulin (Ig) M response typically develops by the 5th–7th day of illness, peaks at 2–3 wk, and resolves within 2 mo. Unfortunately, the accuracy of currently available IgM tests varies widely, and none have been sufficiently evaluated to provide unequivocal evidence of acute HHV-6 infection. Seroconversion of HHV-6 or -7 IgG antibodies in serum samples collected 2–3 wk apart is a more reliable means of establishing primary infection, but is not timely. Fourfold increases or decreases in HHV-6 or -7 IgG antibodies also suggest active infection (primary or reactivated). Because of the high seroprevalence of HHV-6 in the general population, a single positive HHV-6 or -7 IgG test is of no diagnostic significance for diagnosis of acute infection. CMV antibodies can cross react with HHV-6 and HHV-7; therefore, diagnosis of HHV-6 and HHV-7 infections by serologic means requires exclusion of CMV infection.

Identification of HHV-6 or HHV-7 in PBMCs by virus culture firmly establishes the presence of active infection in immunocompetent hosts; association with specific disease is more problematic in immunocompromised patients as a result of a low background rate of viremia. Identification of HHV-6 and HHV-7 by culture requires incubation of PBMCs (with or without co-cultivation with exogenous PBMCs) for days to several weeks, and is presently available only in research laboratories. A commercial HHV-6 rapid (shell-vial) culture is available; it appears comparable to standard virus culture for detection of active HHV-6 infection.

PCR amplification tests for HHV-6 are becoming available and may provide more

timely information for diagnosis. Active, replicating infection is indicated if HHV-6 DNA is detected in acellular specimens such as serum or cerebrospinal fluid. However, detection at other sites (e.g., PBMCs, saliva, and tissues) does not necessarily indicate active infection, because HHV-6 exists in latent form in many tissues after primary infection.

Other diagnostic tests for consideration in selected circumstances include in situ hybridization and immunohistochemistry.

LABORATORY FINDINGS.

White blood cell (WBC) counts of 8,000–9,000?WBCs/µL may be found during the first few days of fever in children with roseola, but by the time the exanthem appears, the WBC count falls to 4,000–6,000?WBCs/µL with a relative lymphocytosis (70–90%). The cerebrospinal fluid in children with HHV-6–associated febrile seizures typically is normal. The cerebrospinal fluid from rare cases of HHV-6–associated meningoencephalitis and encephalitis is characterized by a mild pleocytosis with predominance of mononuclear cells, normal glucose, and normal to slightly elevated protein.

DIFFERENTIAL DIAGNOSIS.

Children with roseola typically present at two different stages of the illness: at the time of fever before the rash (pre-eruptive) and after the rash has appeared. During the pre-eruptive stage, many conditions may be confused with roseola. However, the pattern of fever in a generally well child without significant physical findings, rather precipitous defervescence, and a subsequent rash is unique for roseola. Nonetheless, some patients may not display all these characteristics and conditions may mimic other illnesses.

Roseola is probably most commonly confused with rubella. In contrast to the absence of a distinct prodrome in children with roseola, children with rubella invariably have a mildly symptomatic prodromal period, including prominent occipital and postauricular lymphadenopathy. Lymphadenopathy is an inconsistent finding in roseola; when lymphadenopathy does occur, occipital lymph nodes are more frequently affected than those in the postauricular region. Rubella usually causes only low-grade fever, which is coincident with the exanthem. The rubella rash is typically more extensive than that seen with roseola, and coalescence is more common. A history of exposure is frequently elicited from those in whom rubella develops. Most important, vaccinated persons rarely acquire rubella.

Roseola may be confused with measles. However, the development of an exanthem at the height of the fever, as well as the presence of cough, coryza, conjunctivitis, and Koplik spots on the buccal mucosa in the early stages of measles, differentiates these two illnesses.

Outbreaks of roseola-like illnesses have been associated with many different viruses, most commonly enteroviruses. In summer and fall months, some cases of roseola-like illnesses may be attributable to enteroviruses.

Scarlet fever may also resemble roseola. Important features of scarlet fever are its rarity in infancy, the simultaneous presence of fever and rash, and the discrete, small, sandpaper-like rash lesions.

Drug hypersensitivity is a common condition resembling roseola. Antibiotics are frequently prescribed to children with roseola during the febrile phase before onset of the rash. A child who acquires a drug rash may do so soon after resolution of the fever, which is the characteristic pattern for children with roseola. However, the usually morbilliform nature, pruritus, and resolution after discontinuation of the implicated drug should distinguish a drug rash.

It may be difficult to distinguish central nervous system disease caused by HHV-6 from other causes. Development of a roseola-like illness in association with febrile seizures, meningoencephalitis, or encephalitis makes HHV-6 infection more likely; however, this occurs infrequently.

Hepatitis and heterophile-negative mononucleosis are rarely associated with HHV-6, and other causes for these infections should first be sought.

Treatment.

HHV-6 is inhibited by ganciclovir, cidofovir, and foscarnet (but not acyclovir) at levels that are achievable in serum; HHV-7 is inhibited by cidofovir and foscarnet. Case reports have indicated successes and failures with these drugs; however, prospective trials evaluating the clinical efficacy of antiviral agents for HHV-6 or HHV-7 infections have not been performed.

The generally benign nature of roseola precludes consideration of antiviral therapy. However, future studies may address the need for specific antiviral therapy in those unusual cases of roseola or other forms of HHV-6 infection in which significant morbidity exists, such as children with neurologic complications of roseola or immunocompromised children with severe HHV-6 or HHV-7 infection.

Children in the febrile, pre-eruptive phase of roseola usually are quite comfortable and require little supportive therapy. Those children who are uncomfortable and irritable, or in whom histories of febrile convulsions exists, may benefit from treatment with acetaminophen or ibuprofen. Adequate fluid balance should be maintained in all affected children. Referral should be considered in those unusual circumstances in which serious disease develops, such as encephalitis, hepatitis, or pneumonitis.

Prognosis.

The prognosis for the great majority of children with roseola is excellent, with no obvious sequelae. Before the discoveries of HHV-6 and HHV-7, rare complications of roseola (hemiparesis, mental retardation) were attributable to brain anoxia during prolonged febrile seizures. However, damage resulting from direct viral invasion of the brain, liver, and other organs has been demonstrated for HHV-6. Deaths directly attributable to HHV-6 have been reported in normal as well as immunocompromised patients in whom encephalitis, hepatitis, pneumonitis, disseminated disease, or hemophagocytosis syndrome developed.

Prevention.

Very little information is available on which to base guidelines for prevention of HHV-6 or HHV-7 infection. Experimental evidence suggests that roseola may be transmitted via blood or saliva, and both HHV-6 and HHV-7 are shed in the saliva. It is likely that healthy immune carriers with latent viral infections transmit infection to susceptible infants and children. No specific recommendations for prevention can be made until proper studies have been conducted. No vaccine has been developed.

Chapter 236 - Human Herpesvirus 8

Charles T. Leach

The identification of the newest human herpesvirus, human herpesvirus 8 (HHV-8; also known as **Kaposi sarcoma (KS)– associated herpesvirus**), in 1994 resulted from a search for an infectious agent responsible for KS in patients with AIDS. Further studies have revealed its strong association with KS as well as other rarer malignancies.

Etiology.

HHV-8 is a member of the ?-herpesviruses, which includes Epstein-Barr virus. HHV-8 is an enveloped DNA virus of approximately 165,000 base pairs, and has an overall genomic structure typical for other human herpesviruses. However, unlike most other viruses, the HHV-8 genome contains viral homologues of several human proteins important in regulation of cellular proliferation. It is postulated that these viral proteins contribute to the pathogenesis of HHV-8–associated malignancies.

Epidemiology.

HHV-8 infection is uncommon in healthy children and adults in most developed countries. Rates of HHV-8 infection in HIV-uninfected persons and blood donors in the United States are generally less than 10%, but may be higher in specific areas. HHV-8 infection is more common (15–20%) in certain areas of Greece and Italy. HHV-8 seroprevalence rates are much higher in Brazil, Egypt, and Central Africa, where 40–60% of children are infected.

Approximately one third of HIV-infected homosexual males and more than 80% of HIV-infected homosexual males who acquire KS are infected with the virus. Patients with HIV infection acquired in another manner (e.g., vertically from an HIV-positive mother or through transfusion of blood or blood products) have low rates (0–5%) of HHV-8 infection that are similar to those observed in HIV-uninfected persons and blood donors.

HHV-8 is shed in the saliva of most HHV-8–infected persons, and probably serves as a major source for intrafamilial transmission. Sexual transmission also is important, especially among homosexual males. Rarely, HHV-8 has been transmitted vertically and via blood transfusion. Most HHV-8–associated disease in transplant recipients is caused by reactivated virus, although some infections have been transmitted via the donor organ.

Clinical Manifestations.

Rare reports describe immunocompromised adults with symptoms developing in conjunction with primary HHV-8 infections. In children, one report describes fever and rash in immunocompetent Egyptian infants 1–4 yr of age undergoing primary HHV-8 infection.

Three malignancies occurring primarily in adults with AIDS are strongly associated with HHV-8: KS, multicentric Castleman disease, and primary effusion lymphoma. KS is the most common neoplasm associated with AIDS but also occurs in HIV-uninfected persons living in the Mediterranean region (**classic KS**), in equatorial Africa (**endemic KS**), and in organ transplant recipients (post-transplant KS). Multicentric Castleman disease and primary effusion lymphoma are much rarer lymphoproliferative diseases. Although HHV-8 can be identified in malignant tissue from most patients with these disorders, a clear etiologic link has not yet been firmly established. It has been suggested that HHV-8 may play an indirect role in these malignancies by providing viral analogs of cellular growth factors. There is controversy regarding the role of HHV-8 in development of multiple myeloma in elderly adults.

Diagnosis.

HHV-8 infection can be demonstrated by serologic testing (enzyme immunoassay, immunofluorescence, and Western immunoblotting) or detection of HHV-8 DNA sequences by polymerase chain reaction amplification. Combinations of tests are often used, to maximize accuracy. However, tests are available from only a limited number of commercial laboratories. The virus is not easily cultivated.

Treatment.

Several antiviral compounds inhibit HHV-8 in vitro, including ganciclovir, foscarnet, and cidofovir. However, the benefit of specific antiviral therapy for HHV-8–associated disease has not yet been established. Introduction of highly active antiretroviral therapy has dramatically improved survival for AIDS patients with KS. Other treatment options for KS include cryotherapy, phototherapy, topical retinoic acid, chemotherapy, radiation therapy, and surgery.

Chapter 237 - Influenza Viruses

Peter Wright

Influenza viral infections cause a broad array of respiratory illnesses that are responsible for significant morbidity and mortality in children.

Etiology.

Influenza viruses are members of the family Orthomyxoviridae. They are large, single-stranded RNA viruses with a segmented genome encased in a lipid-containing envelope. The two major surface proteins that determine the serotype of influenza, hemagglutinin and neuraminidase, project as spikes through the envelope. Influenza viruses are divided into three types: A, B, and C. Influenza types A and B are the primary influenzal pathogens and causes of epidemic disease. Influenza type C is a sporadic cause of predominantly upper respiratory tract disease. Influenza types A and B are further divided into serotypically distinct strains that circulate on a yearly basis through the population.

Epidemiology.

Influenza A viruses have a complex epidemiology involving animal hosts that serve as a reservoir for diverse strains with potential for infecting the human population. The segmented nature of the influenza genome allows reassortment

to occur between an animal and human virus when co-infection occurs. Thus, potentially any of 15 hemagglutinins (H) and 9 neuraminidases (N) residing in animal reservoirs may be introduced into humans; influenza A viruses behave epidemiologically as though there were many serotypes. Minor changes within a serotype are termed antigenic drift; major changes in serotype are termed antigenic shift. In addition, migratory avian hosts may be responsible for spread of disease. Recent examples have occurred in Hong Kong with H5N1 and H9N2 viruses. For example, in the winter of 1997, a small outbreak of a virulent avian H5N1 influenza in humans was associated with a high mortality; 6 of 18 patients died. Influenza B has much less capacity for major antigenic change and no identified animal reservoir.

The worldwide epidemiology of influenza viruses demonstrates annual spread between the Northern and Southern hemispheres with the origins of new strains often traced to Asia. When a virus identified by a novel and serologically distinct hemagglutinin or neuraminidase enters the population, there is potential for a pandemic of influenza with excess morbidity and mortality on a global scale in a largely nonimmune population. The most dramatic pandemic in recent history occurred in 1918, when influenza was estimated to have killed more than 20 million people. More common is the almost yearly variation in the antigenic composition of the surface proteins, which confers a selective advantage to a new strain and results in localized epidemics of disease with mortality largely confined to the elderly and to those with underlying cardiopulmonary disease. Each year's strain is novel for infants because they have no pre-existing antibody except for maternally transferred antibody in the very young.

The attack rate and frequency of isolation of influenza is highest in young children. As many as 30–50% of children have serologic evidence of infection in a typical year. Children undergoing primary exposure to an influenza strain have higher levels and more prolonged shedding of the virus than adults, making them extremely effective transmitters of infection. Influenza is a disease of the colder months of the year in temperate climates; spread appears to occur by small-particle aerosol. Transmission through a community is rapid; the highest incidence of illness occurs within 2–3 wk of introduction. Influenza is marked by increased school absenteeism and a yearly peak in sick visits to the pediatrician. Influenza has been implicated in hospital spread of infection and may complicate the original illness that required hospitalization.

On a country or global basis, one or two predominant strains spread to create the annual epidemic. At present, influenza type A strains with the H1N1 and H3N2 serotypes and type B strains are co-circulating, and either type may be predominant in any one year, making predictions about the serotype and severity of the upcoming influenza season difficult. Strain variants are identified by their hemagglutinin and neuraminidase serotypes, by the geographic area from which they were originally isolated, by their isolate number, and by year of isolation. Thus, the influenza vaccine for 2002–2003 was trivalent, having strains identified as A/New Caledonia/20/99 (H1N1), A/Moscow/10/ 99 (H3N2), and B/Hong Kong/330/01.

Pathogenesis.

The virus attaches to sialic acid residues on cells via the hemagglutinin and, via endocytosis, makes its way into vacuoles, where, with progressive acidification, there is fusion to the endosomal membrane and release of the viral RNA into the cytoplasm. The RNA is transported to the nucleus and transcribed. Newly synthesized RNA is returned to the cytoplasm and translated into proteins, which are transported to the cell membrane. This is followed by budding of virus through the cell membrane. The packaging mechanisms for the segmented genome are not well understood. A proteolytic cleavage of the hemagglutinin occurs at some point in the assembly and release of the virus, which is essential for successful reinfection and amplification of virus titer. In humans, this replicative cycle is confined to the respiratory epithelium. With primary infection, virus replication continues for 10–14 days. Implicit in successful replication in the respiratory tract is the assumption that key proteolytic enzymes exist at this site. The effective cleavage of hemagglutinin has been demonstrated by respiratory secretions, but the cellular origin of the enzyme remains undefined.

Influenza causes a lytic infection of the respiratory epithelium with loss of ciliary function, decreased mucus production, and desquamation of the epithelial layer. These changes permit secondary bacterial invasion either directly through the epithelium or, in the case of the middle ear space, through obstruction of the normal drainage through the eustachian tube. Influenza types A and B have been reported to cause myocarditis, and influenza type B can cause myositis. Reye syndrome can result with the use of salicylates for influenza type B infection (Chapter 342).

The exact immune mechanisms involved in termination of primary infection and protection against reinfection are not well understood but may correspond to the induction of cytokines which inhibit viral replication such as interferon and tumor necrosis factor-a. The incubation period of influenza can be as short as 48–72?hr. The extremely short incubation period of influenza and its growth on the mucosal surface pose particular problems for invoking a protective immune response. Antigen presentation must be primarily at mucosal sites acting through the bronchial associated lymphoid tract. The major humoral response is directed against the hemagglutinin. High serum antibody levels generated by inactivated vaccine correlate with protection. Mucosally produced immunoglobulin (IgA) antibodies are presumably directed at the same antigenic sites and are thought to be the most effective and immediate response that can be generated to protect against influenza. Unfortunately, measurable IgA antibodies against influenza persist for a relatively short period, and symptomatic reinfection with influenza can be seen at intervals of 3–4 yr. Although heterotypic immunity can be demonstrated in the mouse through cell-mediated immune mechanisms directed toward common internal proteins, heterotypic immunity has not been shown in humans.

Clinical Manifestations.

Influenza types A and B cause predominantly a respiratory illness. The onset of illness is abrupt and is marked by coryza, conjunctivitis, pharyngitis, and dry cough (Table 237–1). The predominant symptoms may localize anywhere in the respiratory tract, producing an isolated upper respiratory tract illness, croup, bronchiolitis, or pneumonia. More so than any of the other respiratory viruses, influenza is accompanied by systemic signs of high temperature, myalgia, malaise, and headache. Many of these symptoms may be mediated through cytokine production by the respiratory tract epithelium instead of reflecting systemic spread of the virus. The typical duration of the febrile illness is 2–4 days. Cough may persist for longer periods of time, and evidence of small airway dysfunction is often found weeks later. Other family members or close contacts often have a similar illness. Influenza is a less distinct illness in younger children and infants; manifestations may be localized to any region of the respiratory tract. The children may be highly febrile and toxic in appearance, prompting a full diagnostic work-up. Despite the distinctive features of influenza, the illness is often indistinguishable from that caused by other respiratory viruses such as respiratory syncytial virus, parainfluenza viruses, and adenoviruses.

Diagnosis.

The diagnosis of influenza depends on epidemiologic and clinical considerations. In

the context of an epidemic, the clinical diagnosis of influenza in a young child with fever, malaise, and respiratory symptoms can be made with some certainty. The laboratory confirmation of influenza can be made in three ways. If seen early in the illness, virus can be isolated from

the nasopharynx by inoculation of the specimen into embryonated eggs or a limited number of cell lines that support the growth of influenza. The presence of influenza in the culture is confirmed by hemadsorption, which depends on the capacity of the hemagglutinin to bind red cells. Rapid diagnostic tests for influenza A are available that use variations on antigen capture such as an enzyme-linked immunosorbent assay. The diagnosis can be confirmed serologically with acute and convalescent sera drawn around the time of the illness and tested by hemagglutination inhibition.

LABORATORY FINDINGS.

The clinical laboratory abnormalities associated with influenza are nonspecific. A relative leukopenia is frequently seen. Chest radiographs show evidence of atelectasis or infiltrate in about 10% of children.

Treatment.

Two classes of antiviral drugs are effective in the treatment of influenza (Table 237–2). Guidelines for the use of the neuraminidase inhibitors, zanamivir and oseltamivir, are now available for children down to the ages of 7 years and 1 year, respectively. These drugs, given either as an inhalation in the case of zanamivir or orally in the case of oseltamivir, are effective against both influenza A and B strains. The second class of drugs, amantadine and rimantadine, can be used in influenza type A outbreaks. These two antivirals are not effective against influenza B and are not approved for use in children <1 yr of age. Each class of drug must be given within the first 48?hr of symptoms to decrease the severity and duration of influenza. Confusion and inability to concentrate or sleep are seen in some patients given amantadine. Drug resistance develops fairly

TABLE 237-2 -- **Recommended Daily Dosage of Influenza Antiviral Medications for Treatment and Prophylaxis*[*]***

‡Effective only against influenza A strains.

quickly during a course of amantadine or rimantadine therapy, but it is not widespread among circulating viruses. Partial resistance to the neuraminidase inhibitors may occur but is less common. All of these drugs are an adjunct to a strong vaccination program. A family home or schoolroom may be appropriate places to try to prevent secondary illness, particularly where individuals have underlying conditions that predispose them to severe or complicated influenza infection.

Adequate fluid intake and rest are important components in the management of influenza. Acetaminophen or ibuprofen, but not salicylates because of the risk of Reye syndrome (Chapter 342), should be used as antipyretics to control fever. The most difficult question for parents is the appropriate timing of consultation with a health care provider. Bacterial superinfections are relatively common, and in that case antibiotic therapy should be administered. Bacterial superinfections should be suspected with recrudescence of fever, prolonged fever, or deterioration in clinical status. With uncomplicated influenza, children should feel better after the first 48–72?hr.

Complications.

Otitis media and pneumonia are common complications of influenza in young children. Acute otitis media may be seen in up to 25% of cases of culture-documented influenza. Pneumonia accompanying influenza may be a primary viral process. An acute hemorrhagic pneumonia may be seen in the most severe cases, as may have been frequent with the highly virulent strain seen in 1918. The more common cause of pneumonia is probably secondary bacterial infection through the damaged epithelial layer. Unusual clinical manifestations of influenza include acute myositis seen with influenza type B, which follows the acute respiratory illness by 5–7 days and is marked by muscle weakness and pain, particularly in the thigh muscles, and myoglobinuria. Myocarditis also follows influenza, and toxic shock syndrome is associated with influenza type B and staphylococcal colonization. Influenza is particularly severe in children with underlying cardiopulmonary disease, including congenital and acquired valvular disease, cardiomyopathy, bronchopulmonary dysplasia, asthma, cystic fibrosis, and neuromuscular diseases affecting the accessory muscles of breathing. Virus is shed for longer periods of time in children receiving cancer chemotherapy and children with immunodeficiency.

Prognosis.

The prognosis for recovery is excellent, although full return to normal levels of activity and freedom from cough usually requires weeks rather than days.

Prevention.

Influenza vaccine of targeted populations is the best means of prevention of severe disease from influenza. Recommendations for use of influenza vaccine have become progressively broader as the impact of influenza is appreciated in such groups as pregnant mothers and young children. Chemoprophylaxis with the drugs discussed under treatment is a secondary means of prevention.

VACCINE.

An inactivated influenza vaccine becomes available each summer, incorporating changes in formulation that

---

reflect the strains anticipated to circulate in the coming winter. The American Committee on Immunization Practices publishes guidelines for their use each year when the vaccines are formulated and released. Current guidelines include the administration of vaccine intramuscularly to children =6 mo of age as well as adults in groups at high risk for complications of influenza, including residents of long-term care facilities; patients with chronic disorders of the pulmonary or cardiovascular system, including asthma; patients with chronic metabolic diseases (including diabetes mellitus), renal dysfunction, hemoglobinopathies, or immunosuppression (including immunosuppression caused by medications and HIV); and patients receiving long-term aspirin therapy who may be at risk for Reye syndrome after influenza. Vaccination is also recommended for women who will be in the second or third trimester (=14 wk gestation) of pregnancy during the influenza season (October–March). In addition, vaccine is recommended for individuals who may transmit influenza to persons at high risk, including all health care workers and household members of persons in groups at high risk. More recently the recommendations have been extended to encourage vaccination “to the extent logistically and economically feasible” of all healthy children who will be 6–23 months of age during influenza season (October–March) because their risk of hospitalization is similar to the elderly. Annual influenza vaccine is also recommended for all adults over 50 years of age, and all members of households, including children, with persons in groups at high risk.

Because of the decreased potential for causing febrile reactions, only the split-virus vaccine is recommended for children <12 yr of age. Two doses of vaccine (0.25?mL for 6–36 mo of age; 0.5?mL for 3–8 yr of age) at least 1 mo apart are recommended for primary immunization of children <9 yr of age. Live attenuated vaccines that are administered intranasally are in clinical trials and have been demonstrated to have an efficacy comparable to that of inactivated vaccine in adults. Trials in children have shown efficacy of 90%. These vaccines are likely to be licensed soon. Their ease of administration could serve to increase influenza vaccination among children.

CHEMOPROPHYLAXIS.

Amantadine and zanamivir are licensed for prophylaxis of influenza A infections (see Table 237–2). They are recommended for prophylaxis for vaccinated and unvaccinated high-risk patients and their unvaccinated health care providers during influenza A outbreaks in closed settings, for unvaccinated persons and health care providers during community influenza A outbreaks and during the period of peak influenza A activity, for immunodeficient persons, and for those for whom the

influenza vaccine is contraindicated.

Chapter 238 - Parainfluenza Viruses

Peter Wright

Viruses in the parainfluenza family are common causes of respiratory illness in infants and young children. They cause a spectrum of upper and lower respiratory tract illnesses, but are particularly associated with laryngotracheitis, bronchitis, and croup.

Etiology.

The parainfluenza viruses are members of the Paramyxoviridae family. There are four viruses in the parainfluenza group that cause illness in humans; they are designated types 1–4. The viruses have a nonsegmented, single-stranded RNA genome with a lipid-containing envelope derived from budding through the cell membrane. The major antigenic moieties are envelope spike proteins that exhibit hemagglutinating (HN protein) and cell fusion (F protein) properties.

Epidemiology.

Parainfluenza viruses are spread from the respiratory tract by aerosolized secretions or direct hand contact with secretions. By 3 yr of age, most children have experienced infection with types 1, 2, and 3. Type 3 is endemic and can cause disease in the infant younger than 6 mo. Serious illness is seen with parainfluenza type 3 in immunocompromised patients. Types 1 and 2 occur in a seasonal pattern in the summer and fall and alternate years in which their serotype is most prevalent. Parainfluenza type 4 is more difficult to grow in tissue culture; thus, its epidemiology is less well defined. However, it does not appear to be a major cause of illness.

Pathogenesis.

Parainfluenza viruses replicate in the respiratory epithelium without evidence of systemic spread. The propensity to cause illness in the upper large airways is presumably related to enhanced replication in the larynx, trachea, and bronchi compared with other viruses. The destruction of cells in the upper airways can lead to secondary bacterial invasion and resultant bacterial tracheitis. Eustachian tube obstruction can lead to secondary bacterial invasion of the middle-ear space and

acute otitis media.

Illness caused by parainfluenza occurs shortly after inoculation with the virus. The mechanisms by which viral injury occurs are not known. Some parainfluenza viruses induce cell-to-cell fusion. During the budding process, cell membrane integrity is lost, and viruses can induce cell death through the process of apoptosis. The severity of illness correlates with the amount of viral shedding. Immune destruction of virally infected cells may also occur, but appears to be less important with mucosal than systemic infection. The level of immunoglobulin A antibody is the best predictor of susceptibility to infection. Reinfection is seen particularly with parainfluenza type 3 as mucosal immunity wanes. The inability of children with serious T-cell defects to clear parainfluenza type 3 suggests a cell-mediated component of immunity.

Clinical Manifestations.

Most parainfluenza virus infections are confined to the upper respiratory tract (Table 238–1). This relatively mild-appearing illness is belied by a spectrum of rarer but more serious illnesses that result in hospitalization. The parainfluenza viruses account for 50% of hospitalizations for croup and 15% of cases of bronchiolitis and pneumonia. Parainfluenza type 1 causes more cases of croup, whereas parainfluenza type 3 causes a broad spectrum of lower respiratory tract diseases.

Parainfluenza virus infections are not associated with fever. Aside from low-grade fever, systemic complaints are rare. The illness usually lasts 4–5 days; however, virus may be recovered in low titers for 2–3 wk. Rarely, parainfluenza viruses have been implicated in parotitis.

TABLE 238-1 -- Diagnoses and Signs and Symptoms of Children Younger than 5 Yr of Age with Parainfluenza Infections

Diagnoses	Type 1 (n = 77)	Type 2 (n = 33)	Type 3 (n = 157)	Other (n = 19)
Upper Respiratory	90%	94%	89%	84%
Common cold	31%	42%	32%	42%
Pharyngitis	21%	18%	10%	11%[*]
Acute otitis media	38%	30%	52%	32%[†]
Lower Respiratory	17%	15%	15%	21%
Croup (laryngotracheobronchitis)	16%	6%	5%	21%[‡]
Bronchiolitis	1%	9%	6%	0%
Signs and Symptoms				
Coryza	74%	75%	83%	83%
Conjunctivitis	36%	36%	36%	44%
Cough	73%	67%	81%	77%
Hoarseness	28%	18%	11%	39%[§]
Rales or rhonchi	6%	15%	15%	11%
Wheezing	9%	12%	4%	5%
Temperature > 38°C	33%	16%	38%	6%
Temperature > 39°C	8%	6%	10%	0%
Irritability	47%	30%	54%	72%[¶]
Anorexia	36%	36%	36%	44%
Vomiting	15%	15%	24%	22%
Diarrhea	21%	15%	14%	22%

Diagnosis.

The diagnosis of parainfluenza virus infection in children is usually based only on clinical and epidemiologic criteria. The virus should be specifically sought in persistent pneumonias in immunosuppressed children. The radiographic “steeple sign” of progressive narrowing of the subglottic region is characteristic of parainfluenza virus respiratory tract infections.

LABORATORY FINDINGS.

There are no distinctive laboratory findings. The laboratory diagnosis of parainfluenza virus infection can be accomplished by inoculation of nasal secretions into tissue culture, with presumptive diagnosis based on finding a hemadsorbent agent and final serologic diagnosis based on hemadsorption inhibition. Direct

immunofluorescent staining is available in some centers for rapid identification of virus antigen in oropharyngeal sections.

Treatment.

The possibility of rapid respiratory compromise during severe croup should influence the level of care given (Chapter 371). Careful attention to symptomatic care is important. Parents should be provided a description of the signs of increasing respiratory distress that should lead to reassessment by a health care provider. Humidification and exposure to cold air are both classically associated with a decrease in mucosal edema and liquefaction of secretions that may help to relieve obstruction; however, their value has not been shown in controlled trials. Aerosolized racemic epinephrine may temporarily improve aeration, but has the possibility of rebound. Aerosolized or systemic corticosteroids should be part of the management of croup in the emergency room setting and after hospitalization. The indications for antibiotics are limited to well-documented secondary bacterial infections of the middle ears or lower respiratory tract.

Ribavirin has some antiviral activity against parainfluenza virus, and should be considered in the immunocompromised child with persistent parainfluenza viral pneumonia.

Complications.

In children with fever or more severe respiratory compromise, the possibility of a bacterial tracheitis with purulent infection below the epiglottis and vocal cords should be considered. The high frequency of otitis media complicating parainfluenza virus indicates that careful pneumatic otoscopy should be performed in all children with suspected parainfluenza virus infection.

Prognosis.

The prognosis for full recovery is excellent in the normal child. No long-term pulmonary residua of parainfluenza virus infection have been described.

Prevention.

Work is progressing with both live and subunit parainfluenza type 3 vaccines. The live vaccine candidates include a cold-adapted virus of human origin and a bovine parainfluenza virus, which is attenuated because of host range adaptation. The measure of protection afforded by vaccines will be difficult to assess because symptomatic reinfection is seen and the frequency of serious infection in the general population is low. Nonetheless, it is clear that prevention of acute respiratory illness that results from parainfluenza virus is a worthwhile goal.

Chapter 239 - Respiratory Syncytial Virus

Kenneth McIntosh

Respiratory syncytial virus (RSV) is the major cause of bronchiolitis (Chapter 371) and pneumonia in children younger than 1 yr of age (Chapter 389). It is the most important respiratory tract pathogen of early childhood.

Etiology.

RSV is a medium-sized, membrane-bound RNA virus that develops in the cytoplasm of infected cells and matures by budding from the plasma membrane. It belongs to the family Paramyxoviridae, along with parainfluenza, mumps, and measles viruses, but is the sole member of the genus *Pneumovirus* that infects human beings. Although different strains of RSV show some antigenic heterogeneity, this variation is primarily in one of the two surface glycoproteins (G protein), and it is not clear that this degree of difference is clinically or epidemiologically significant. RSV grows in a number of types of tissue culture, in which it produces characteristic syncytial cytopathology.

Epidemiology.

The occurrence of annual outbreaks and the high incidence of infection during the first months of life are unique among human viruses. RSV is distributed worldwide and appears in yearly epidemics. In temperate climates, these epidemics occur each winter and last 4–5 mo. During the remainder of the

year, infections are sporadic and uncommon. In the Northern Hemisphere, epidemics usually peak in January, February, or March, but peaks have been recognized as early as December and as late as June. At these times, hospital admissions for bronchiolitis and pneumonia of children younger than 1 yr increase and decrease in proportion to the number of RSV infections in the community. In the tropics, the epidemic pattern is less clear.

Transplacentally transmitted anti-RSV antibody, when present in high concentration, has some protective effect. This probably accounts for the low frequency of severe infections in the first 4–6 wk of life, except in infants born prematurely who receive less than a full complement of maternal immunoglobulin (Ig) G. Nevertheless, serum antibody is not fully protective, and the age at which an infant undergoes first infection depends also on the opportunities for exposure. It is estimated that in an urban setting about half of the susceptible infants undergo primary infection in each epidemic. Thus, infection is almost universal by the 2nd birthday. Reinfection occurs at a rate of 10–20% per epidemic throughout childhood; the frequency is lower in adults. In situations of high exposure such as daycare centers, attack rates are higher: nearly 100% for first infections and 60–80% for second and subsequent infections.

Estimates of the severity of primary infections have emerged from studies of outbreaks in nurseries and institutions. Under these circumstances, asymptomatic infection is rare. Most infants experience coryza and pharyngitis, usually with fever and occasionally with otitis media. In 10–40% of patients, the lower respiratory tract is involved to a varying degree. Bronchitis, bronchopneumonia, and bronchiolitis all occur. Calculations based on hospital admissions in the United States and Britain yield a ratio of 1–3 infants hospitalized with bronchiolitis or pneumonia for every 100 primary infections with the virus.

Reinfection may occur as early as a few weeks after recovery, but usually takes place during subsequent annual outbreaks. The severity of illness during reinfection is usually lower, and appears to be a function of both partial immunity and increased age. Nevertheless, instances of severe RSV bronchiolitis occurring twice in succession have been documented.

Bronchiolitis is the most common clinical diagnosis in infants hospitalized with RSV infections, although the syndrome is often indistinguishable from RSV pneumonia in infants, and, indeed, the two frequently coexist. All RSV diseases of the lower respiratory tract (excluding croup) have their highest incidence from 2–7 mo of age and decrease in frequency thereafter. The syndrome of bronchiolitis becomes uncommon after the 1st birthday; acute infective wheezing attacks after that age are often termed “wheezy bronchitis,” “asthmatoid bronchitis,” or simply asthma attacks. Viral pneumonia is a persistent problem throughout childhood, although RSV becomes less prominent as the etiologic agent after the 1st year. RSV is responsible for 45–75% of cases of bronchiolitis, 15–25% of childhood pneumonias, and 6–8% of cases of croup.

Bronchiolitis and pneumonia resulting from RSV are more common in boys than in girls by a ratio of about 1.5:1. Racial factors make little difference. Lower respiratory tract involvement occurs more often and earlier in life in lower socioeconomic groups and in crowded living conditions.

The incubation period from exposure to first symptoms is about 4 days. The virus is excreted for variable periods, probably depending on severity of illness and immunologic status. Most infants with lower respiratory tract illness shed virus for 5–12 days after hospital admission. Excretion for 3 wk and longer has been documented. Spread of infection occurs when large, infected droplets, either airborne or conveyed on hands, are inoculated in the nose or conjunctiva of a susceptible subject. RSV is probably introduced into most families by schoolchildren undergoing reinfection. Typically, in the space of a few days, older siblings and one

or both parents acquire colds, but the infant becomes more severely ill with fever, otitis media, or lower respiratory tract disease.

Nosocomial infection during RSV epidemics is an important concern. Virus is usually spread from child to child on the hands of caregivers. Adults undergoing reinfection have also been implicated in spread of the virus.

Pathogenesis.

Bronchiolitis is characterized by virus-induced necrosis of the bronchiolar epithelium, hypersecretion of mucus, and round cell infiltration and edema of the surrounding submucosa. These changes result in formation of mucous plugs obstructing bronchioles with consequent hyperinflation or collapse of the distal lung tissue. In interstitial pneumonia, infiltration is more generalized, and epithelial necrosis may extend to both the bronchi and the alveoli. Infants are particularly apt to experience small airway obstruction because of the small size of the normal bronchioles.

Immunologic injury is likely a factor in the pathogenesis of bronchiolitis caused by RSV. A large number of soluble factors (interleukins, leukotrienes, and chemokines) with the potential to stimulate inflammation and tissue damage are liberated during RSV infection. In animal models, reactive T cells are involved both in the pathogenesis of lung damage and in recovery from infection. In many children, RSV bronchiolitis is followed by recurrent wheezing episodes, and certain markers found during the acute episode, particularly the presence of eosinophils and eosinophilic cationic protein in blood, appear to be associated with such recurrences.

It is not clear how often superimposed bacterial infection plays a pathogenic role in RSV lower respiratory tract disease. The present view is that RSV-induced bronchiolitis in infants is an exclusively viral disease and that bacteria are of little importance even when the disease is accompanied by atelectasis or interstitial pneumonia.

Clinical Manifestations.

The first signs of infection of the infant with RSV are rhinorrhea and pharyngitis. Cough may appear simultaneously but more often after an interval of 1–3 days, at which time there may also be sneezing and a low-grade fever. Soon after the cough develops, the child begins to wheeze audibly. If the disease is mild, the symptoms may not progress beyond this stage. Auscultation often reveals diffuse rhonchi, fine rales or crackles, and wheezes. Abundant, clear rhinorrhea usually persists throughout the illness, with intermittent fever. Roentgenograms of the chest at this stage are frequently normal.

If the illness progresses, cough and wheezing increase and air hunger ensues with increased respiratory rate, intercostal and subcostal retractions, hyperexpansion of the chest, restlessness, and peripheral cyanosis. Signs of severe, life-threatening illness are central cyanosis, tachypnea of more than 70 breaths/min, listlessness, and apneic spells. At this stage, the chest may be greatly hyperexpanded and almost silent to auscultation because of poor air exchange.

Chest radiographs of infants hospitalized with RSV bronchiolitis are normal in about 10% of cases; air trapping or hyperexpansion of the chest is evident in about 50%. Peribronchial thickening or interstitial pneumonia is seen in 50–80%. Segmental consolidation occurs in 10–25%. Pleural effusion is rarely, if ever, seen.

In some infants, the course of the illness may be more like that of pneumonia with the prodromal rhinorrhea and cough followed by dyspnea, poor feeding, and listlessness, with a minimum of wheezing and hyperexpansion. Although the clinical diagnosis is pneumonia, wheezing is often present intermittently and the chest roentgenogram may show air trapping.

Fever is an inconstant sign in RSV infection. Otitis media, with viral nucleic acid detectable in middle ear fluids, is common. Rash and conjunctivitis each occur in a few cases. In young infants, particularly those who were born prematurely, periodic breathing and apneic spells have been distressingly

frequent signs, even with relatively mild bronchiolitis. It is likely that a small portion of deaths included in the category of sudden infant death syndrome are due to RSV infection.

RSV infections in profoundly immunocompromised hosts may be severe at any age. The mortality associated with RSV pneumonia after bone marrow or solid organ transplantation is 50% or higher. RSV infection does not seem to be severe in HIV-infected patients.

Diagnosis.

Bronchiolitis is a clinical diagnosis. Causation by RSV can be suspected with varying degrees of certainty from the clinical picture, the season of the year, and the presence of a typical outbreak at the time. Another helpful epidemiologic feature is the presence of colds in older household contacts, because RSV frequently reinfects and produces symptoms in older children and adults.

Routine laboratory tests offer little helpful information in most cases of bronchiolitis or pneumonia caused by RSV. The white cell count is normal or elevated, and the differential count may be normal with either a neutrophilic or mononuclear predominance. Bacterial cultures of the throat grow normal flora. Hypoxemia is frequent and tends to be more marked than anticipated on the basis of the clinical findings. When it is severe, it may be accompanied by hypercapnia and acidosis.

The diagnostic dilemma of greatest import is the question of possible bacterial or chlamydial involvement, because such presence dictates the possible use of antimicrobials. When bronchiolitis is clinically mild or when infiltrates are absent by roentgenogram, there is little likelihood of a bacterial component. In infants 1–4 mo of age, interstitial pneumonitis may be caused by *Chlamydia trachomatis* (Chapter 208.3). In *C. trachomatis* pneumonia, there may be a history of conjunctivitis, and the illness tends to be of subacute onset. Coughing and rales are prominent; wheezing is not. There may also be eosinophilia. Fever and rhinorrhea are usually

absent.

Consolidation without other signs or with pleural effusion is considered of bacterial origin until proved otherwise. Other signs suggesting bacterial pneumonia are elevation of the neutrophil count, depression of the white cell count in the presence of severe disease, ileus or other abdominal signs, pleuritic pain, high temperature, and circulatory collapse. In such instances, there is rarely any doubt about the need for antibiotics.

Definitive diagnosis of RSV infection is based on the detection of virus or viral components in respiratory secretions. An aspirate of mucus or a nasopharyngeal wash from the child's posterior nasal cavity is the optimal specimen. A nasopharyngeal swab is also acceptable. A tracheal aspirate is unnecessary. The specimen should be placed on ice, taken directly to the laboratory, and processed for antigen detection or inoculated onto susceptible cell monolayers.

Treatment.

In uncomplicated cases of bronchiolitis, treatment is symptomatic. Humidified oxygen is usually indicated for hospitalized infants because most are hypoxic. Many infants are slightly to moderately dehydrated; therefore, fluids should be carefully administered in amounts somewhat greater than maintenance. Often intravenous or tube feeding is helpful when sucking is difficult due to tachypnea. Infants may breathe more easily when propped up at an angle of 10–30 degrees.

A trial of epinephrine administered either parenterally or by aerosol may relieve wheezing and improve clinical status, and should be repeated if initial benefit is shown. Corticosteroids are not indicated except in older children with an established diagnosis of asthma.

In most instances antibiotics are not useful, and their indiscriminate use in presumed viral bronchiolitis and pneumonia should be discouraged. Interstitial pneumonia in infants 1–4 mo old may be chlamydial; therefore, erythromycin (40?mg/kg/24?hr) or azithromycin (10?mg/kg on day 1, 5?mg/kg on days 2–5) may be beneficial. Parenteral antibiotics are indicated for older infants with interstitial pneumonia, when consolidation is found, and for critically ill children.

The antiviral drug ribavirin, delivered by **small-particle aerosol** for 3–5 days, probably has a modest beneficial effect on the course of RSV pneumonia. Shortened hospital stay and reduced mortality have not been demonstrated, however, and trials in intubated infants have not shown efficacy. Its use is, therefore, rarely indicated except for selected cases of severe immunodeficiency, in which unrestricted viral replication is clearly important in the pathogenesis of severe disease.

Intravenous immunoglobulin prepared from plasma with high neutralization antibody titers (RSV-IGIV), as well as humanized monoclonal antibody, palivizumab, have been used to treat severely immunodeficient patients with pneumonia and RSV infection. Although there is no clear evidence of efficacy, such treatment does reduce the titer of virus in the respiratory tract and may offer a rational therapeutic approach in situations in which the prognosis is otherwise poor.

Prognosis.

The mortality of hospitalized infants with RSV infection of the lower respiratory tract is about 2%. Almost all deaths occur in young, premature infants or those with underlying disease of the neuromuscular, pulmonary, cardiovascular, or immunologic system.

Many children with asthma have a history of bronchiolitis in infancy. There is recurrent wheezing in 33–50% of children with typical RSV bronchiolitis in infancy. In patients older than 1 yr with bronchiolitis, there is an increasing probability that, although the episode may be virus induced, this is the first of multiple wheezing attacks that will later be called asthma.

As mentioned, RSV infection in profoundly immunodeficient or immunosuppressed individuals of any age may, if clinical pneumonia occurs, carry a mortality rate as high as 50%.

Prevention.

Within the hospital, the most important preventive measures are aimed at blocking nosocomial spread. During RSV season, high-risk infants should be separated from infants with respiratory symptoms. Separate gowns and gloves and careful handwashing should be used for the care of all infants with suspected or established RSV infection.

PASSIVE IMMUNOPROPHYLAXIS.

Administration of either palivizumab (15?mg/kg intramuscularly), a monoclonal antibody against RSV, or high-titered RSV intravenous immunoglobulin (RSV-IVIG; 750?mg/kg) is recommended for protecting high-risk children against serious complications from RSV disease. Immunoprophylaxis reduces the frequency and total days of hospitalization for RSV infections in high-risk infants. These agents are administered monthly from the beginning (October–December) to the end (March–May) of the RSV season. Palivizumab is preferred for most children because of ease of intramuscular administration and lack of interference with live virus vaccinations (measles-mumps-rubella and varicella). RSV-IVIG provides some protection against other respiratory pathogens and may be substituted for IVIG during the RSV season for children with immunodeficiency receiving monthly IVIG.

The cost-effectiveness of prophylaxis depends on the health care setting and the risk of the individual child. In the United States, candidates for immunoprophylaxis include infants with lung disease and infants who were born very prematurely. Children younger than 2 yr with bronchopulmonary dysplasia requiring supplemental oxygen therapy currently or within the 6 mo before the RSV season should receive prophylaxis for the first two RSV seasons if they have severe lung disease and only the first RSV season for less severe lung disease. Infants without bronchopulmonary dysplasia should receive prophylaxis up to 12 mo of age if they were born at 28 wk of gestation or earlier and up to 6 mo of age if they were born at 29–32 wk of gestation. One dose of immunoprophylaxis may be considered for premature infants to be discharged from the hospital during the RSV season. RSV-IVIG is contraindicated

and palivizumab is not recommended

for children with cyanotic congenital heart disease. Adverse events with palivizumab are uncommon.

VACCINE.

There is not currently a vaccine against RSV. Vaccine development for RSV has proceeded cautiously since the experience in the 1960s with an alum-precipitated formalin-inactivated vaccine. This vaccine was excellent for inducing serum antibodies, but vaccinees had augmented disease after natural infection. Live, attenuated vaccines have produced unacceptable symptoms or reverted to wild-type virus. Current candidate vaccines are either purified subunit vaccines against one of the surface proteins or attenuated, cold-adapted live vaccines.

Chapter 240 - Adenoviruses

Kenneth McIntosh

Adenoviruses cause 5–8% of acute respiratory disease in infants, plus a wide array of other syndromes, including pharyngoconjunctival fever, follicular conjunctivitis, epidemic keratoconjunctivitis, myocarditis, hemorrhagic cystitis, acute diarrhea, intussusception, and encephalomyelitis. Adenoviral pneumonia may have serious long-term sequelae, including bronchiolitis obliterans. Only one third of the 49 serotypes have been associated with disease.

Etiology.

The Adenoviridae are DNA viruses of intermediate size, which are classified into subgenera A to F. The virion has an icosahedral coat (capsid) made up of 252 subunits (capsomers) of which 240 are "hexons" and 12 are "pentons." The hexons have a cross reacting antigen common to all mammalian adenoviruses. The penton confers type specificity, and antibody to it is protective. Adenoviruses can also be classified by their characteristic DNA "fingerprints" on gels after being digested with restriction endonucleases, and this classification generally conforms to their antigenic types.

All adenovirus types, except types 40 and 41, grow in primary human embryonic kidney cells, and most grow in HEp-2 or HeLa cells, producing a typical destructive cytopathic effect. Types 40 and 41 (and other serotypes as well) grow in 293 cells, a line of human embryonic kidney cells into which certain "early" adenovirus genes have been introduced.

Many adenovirus types, but particularly the common childhood types (1, 2, and 5), are shed for prolonged periods from both the respiratory and gastrointestinal tracts. These types also establish low-level and chronic infection of the tonsils and adenoids.

Epidemiology.

Adenoviral infections are distributed worldwide. They occur year-round but are most prevalent in spring or early summer and again in midwinter in temperate climates. Certain types tend to occur in epidemics, notably types 4 and 7 in outbreaks of febrile respiratory disease, types 3, 7, and 21 in severe pneumonia; type 3 in pharyngoconjunctival fever; type 11 in hemorrhagic cystitis; and types 8, 19, and 37 in epidemic keratoconjunctivitis. For unexplained reasons, adenovirus types 3 and 7 cause severe epidemics of pneumonia in the children of northern China and Korea, with mortality rates in hospitalized cases of 5–15%.

More than 60% of school-aged children have antibodies to the common respiratory types. Almost all adults have serum antibody to types 1–7. Spread occurs by the respiratory and fecal-oral routes, although it is not clear whether spread is by large- or small-particle aerosol. Hospital outbreaks of respiratory disease and keratoconjunctivitis have been described.

Pathogenesis.

Adenoviruses are among the few "respiratory" viruses that grow well in the epithelium of the small intestine. Although mucosal surfaces are the primary target early in infection and typically the site of the most common pathology, viremia probably occurs frequently, with accompanying fever.

Adenoviral pneumonia produces characteristic microscopic changes, with dense lymphocytic infiltrates, destruction of the bronchial and bronchiolar epithelium, focal necrosis of mucous glands, hyaline membrane formation, and several types of nuclear inclusion bodies.

Clinical Manifestations.

Adenoviruses cause a wide array of clinical syndromes.

ACUTE RESPIRATORY DISEASE.

This is the most common manifestation of adenovirus infection in children and adults. Acute adenovirus respiratory tract infections in infants and children are not clinically distinctive and are usually caused by types 1, 2, 3, 5, or 6. Primary infections in infants are frequently associated with fever and respiratory symptoms and are complicated by otitis media in more than half of the patients. Adenovirus respiratory infections are associated with a significant incidence of diarrhea.

Pharyngitis due to adenovirus typically has symptoms of coryza, sore throat, and fever. Adenoviruses can be identified in 15–20% of children with isolated pharyngitis, mostly in preschoolers and infants.

Pneumonia is uncommon, but 7–9% of hospitalized children with acute pneumonia have adenovirus infection. Any of the "respiratory" types can cause pneumonia, but severe infections are most likely due to type 3, 7, or 21. Such infections have a mortality as high as 10%, and survivors may have residual airway damage, manifested by bronchiectasis, bronchiolitis obliterans, or, rarely, pulmonary fibrosis. Neonatal adenovirus pneumonia occurs rarely, but may be severe or fatal.

A *pertussis-like syndrome* has been described in association with adenovirus infections. In these cases, adenoviruses frequently accompany *Bordetella pertussis*

as co-infecting agents, but occasionally they may be causative on their own.

Pharyngoconjunctival fever is a clinically distinct syndrome that occurs particularly in association with type 3 adenovirus. Features include a high temperature that lasts 4–5 days, pharyngitis, conjunctivitis, preauricular and cervical lymphadenopathy, and rhinitis. Nonpurulent conjunctivitis occurs in 75% of patients and is manifested by inflammation of both the bulbar

and palpebral conjunctivae of one or both eyes; it often persists after the fever and other symptoms have resolved. Headache, malaise, and weakness are common, and there is considerable lethargy after the acute stage.

CONJUNCTIVITIS AND KERATOCONJUNCTIVITIS.

Adenovirus is one of the most common causes of follicular conjunctivitis, which is a relatively mild illness, and keratoconjunctivitis, which may occur in epidemics and is associated with infection by adenovirus types 8, 19, and 37. Keratitis begins as the conjunctivitis wanes, and may cause corneal opacities that last several years.

MYOCARDITIS.

In several series of acute myocarditis or idiopathic cardiomyopathy, investigated by the application of polymerase chain reaction (PCR) in the search for microbial agents, adenovirus has been found as commonly as, or more commonly than, nonpolio enteroviruses. It is widely assumed that adenovirus has an important etiologic role in this disease. It has also been associated with heart transplant rejection and with some cases of endocardial fibroelastosis.

GASTROINTESTINAL INFECTIONS.

Adenoviruses can be found in the stools of 5–9% of children with acute diarrhea. About one half of these are the “enteric” types, 40 or 41. It is also clear that enteric infection with any adenovirus serotype is often asymptomatic, so the causative role in these episodes is frequently uncertain.

The pathogenesis of intussusception is thought by many to include enlarged lymph nodes as an initiating factor. Adenoviruses have been recovered from mesenteric lymph nodes or appendices at surgery and also from surface cultures in a higher percentage of children with intussusception than of controls. Adenoviruses have also been found in the appendices of children with appendicitis.

HEMORRHAGIC CYSTITIS.

This syndrome has a sudden onset of bacteriologically sterile hematuria, dysuria, frequency, and urgency lasting 1–2 wk. Infection with adenovirus types 11 and 21 has been found in some affected children and young adults.

REYE SYNDROME AND REYE-LIKE SYNDROMES.

Typical Reye syndrome has followed confirmed adenovirus infection of several serotypes, particularly in very young children. In addition, several cases of a Reye-like syndrome have been reported, all of which are caused by infection with adenovirus type 7. The latter disease, which is frequently fatal, is characterized by severe bronchopneumonia, hepatitis, seizures, and disseminated intravascular coagulation. Circulating adenovirus penton antigen has been found in several patients and has been implicated in the pathogenesis.

INFECTIONS IN IMMUNOCOMPROMISED HOSTS.

Adenoviruses are important pathogens in immunocompromised hosts with either B- or T-cell deficiencies. In B-cell–deficient (hypogammaglobulinemic) patients, a chronic meningoencephalitis similar to that caused by enteroviruses has been described. In T-cell–deficient patients, regardless of whether this deficiency is congenital, acquired, or iatrogenic, prolonged diarrhea is common, and fulminant hepatitis and pneumonia, frequently with a fatal outcome, have been described. There is also a close association between adenovirus infection and both hemorrhagic cystitis and tubulointerstitial nephritis in immunocompromised children, particularly following bone marrow transplantation.

Diagnosis.

The laboratory diagnosis of adenovirus infection in children may be made by immunohistology or suggestive pathologic changes in biopsy material, detection of virus by culture or PCR, demonstration of an increase in antibody titers, or a combination of virus detection and serologic testing. PCR is a very useful method in the detection of adenovirus in biopsy tissues. If virus is found in a “privileged” site, such as blood, urine, or cerebrospinal fluid, or in a biopsy of the lung or liver, the implication of infection with disease and organ damage is strong. Likewise, detection of certain adenovirus types in respiratory secretions (type 7 or 21) probably indicates their etiologic involvement. The presence of untyped virus or the common childhood types (1, 2, and 5) in respiratory secretions or stool does not, however, indicate clinical adenovirus infection because these viruses may be excreted chronically and asymptomatically. In these instances, discovery of a coincident increase in antibody is helpful in assigning a specific adenovirus type to disease. Adenovirus infection may also be considered etiologic if an increase in antibody is found between sera drawn in the acute stage and in convalescence from a patient with an appropriate illness. Adenovirus infection often results in a high erythrocyte sedimentation rate and white blood cell count.

Treatment.

There is interest in the possible role of cidofovir, a renal-toxic antiviral drug that requires intravenous administration, in treatment of severe adenovirus infections. Ribavirin can inhibit viral growth of some strains in vitro, but evidence of its clinical

efficacy is lacking.

Prevention.

Vaccines that contain either killed or live virus have been developed to prevent type 4 and 7 infections in military recruits. These vaccines have not, however, been used in children.

Chapter 241 - Rhinoviruses

Kenneth McIntosh

Rhinoviruses are collectively the most common cause of the "common cold" in adults. They are also very common in young children, but because of the frequency of other viral respiratory tract infections in this age group, their relative importance is somewhat less than in adults. They are difficult to grow in tissue culture, however, and studies using polymerase chain reaction (PCR) indicate that their frequency and importance in respiratory illnesses are considerably greater than was thought.

Etiology.

There are 101 serologically distinct rhinoviruses (numbered 1–100, and subtype 1A), members of the Picornaviridae family of small RNA viruses. They are best identified in clinical samples by PCR performed on nasal secretions from infected individuals. Tissue culture is approximately one third as sensitive as PCR. Routine serologic testing for development of antibody is not practical because of the multiplicity of serotypes.

Not all rhinovirus infections are associated with symptoms, even in infants and children. In longitudinal studies, 75% of pediatric rhinovirus infection (detected by culture) is associated with illness, usually rhinitis or pharyngitis. Rhinoviruses have been found in middle ear fluids during acute otitis media, and they can also be associated with serious lower respiratory tract disease, particularly in very young infants and those with underlying illnesses. They are frequent precipitators of asthmatic attacks.

Epidemiology.

Rhinoviruses are distributed worldwide with no predictable pattern of infection by serotype. Multiple types may be present in a community at one time.

In temperate climates, the incidence of rhinovirus infection peaks in September and again in April or May, but infections occur year-round. The peak incidence in the tropics occurs during the rainy season.

Rhinoviruses are recovered in highest concentration in nasal secretions, and experimental infection is most easily accomplished by nasal or conjunctival instillation. Virus persists for several hours in secretions on hands or other surfaces. Transmission occurs when infected secretions carried on contaminated fingers are rubbed into the nasal or conjunctival mucosa. Evidence also implicates spread through prolonged contact with aerosols produced by talking, coughing, or sneezing.

Pathogenesis.

Rhinoviruses, like other picornaviruses, infect cells only after interaction with specific cell receptors. For most rhinovirus types, this is ICAM-1, an intercellular adhesion molecule present on the epithelium covering the adenoids (lymphoepithelium) and on other epithelial cells of the nose after stimulation by various interleukins (interferon-a, tumor necrosis factor, interleukin 1). Thus, for these types, infection probably begins in the nasopharynx and then, as interleukins are produced, spreads forward to the nasal mucosa. The peak nasal inflammatory response occurs when virus growth is at its greatest, 2–4 days after experimental infection, and is accompanied by the production of multiple proinflammatory mediators. Immune responses include specific nasal immunoglobulin (Ig) A and serum IgG antibody, which may contribute to modifying the illness and limiting viral shedding.

Clinical Manifestations.

The primary clinical response to rhinovirus infection is the common cold (see Chapter 364). There is an incubation period of 2–4 days; then sneezing, nasal obstruction and discharge, and sore throat ensue. Cough and hoarseness occur in 30–40% of cases. Fever is neither as frequent nor as high as in primary infections with respiratory syncytial virus, parainfluenza virus, influenza virus, or adenovirus. Symptoms are worse in the first 2–3 days of illness and last for 1 wk in a majority of patients; they persist for more than 14 days in 35% of young children.

Rhinovirus RNA has been found in the middle-ear fluid of 24% of children with acute otitis media, often in conjunction with bacteria.

Diagnosis.

Because other viral agents can produce the same manifestations, a clinical diagnosis is only presumptive but is usually adequate. Bacterial antigen testing or cultures should be performed to exclude streptococcal nasopharyngitis if this is suspected (see Chapter 366). PCR is the most sensitive method for identifying rhinoviruses in respiratory samples, but laboratory diagnosis is not practical under ordinary circumstances.

Treatment.

Relief of acute symptoms may be provided by acetaminophen or ibuprofen for antipyresis and mild analgesia and by saline or decongestant (for children >6 mo of

age) nose drops used for a short time for nasal discharge and obstruction.

Several antiviral drugs have been developed with potent activity against rhinoviruses, such as pleconaril. Although these drugs reduce the titer of virus in the nose, they do not lessen symptoms or decrease the duration of illness. It seems likely that successful treatment will have to target the host response as well as the virus.

Complications.

Otitis media and sinusitis are common complications. In one study, rhinoviruses were the most common virus recovered from the middle-ear fluids of infants and children with otitis media. In very young infants, bronchiolitis may occur. Rhinoviruses are the most common cause of acute exacerbations of asthma in school-aged children.

Prevention.

The best approach to reducing spread includes careful handwashing and avoidance of manual nose and eye manipulation.

Chapter 242 - Rotavirus and Other Agents of Viral Gastroenteritis

Dorsey M. Bass

Diarrhea is probably the leading cause of childhood mortality in the world, accounting for 5–10 million deaths per year. In early childhood, the single most important cause of severe dehydrating diarrhea is rotavirus infection. Rotavirus and other gastroenteritis viruses not only are major causes of pediatric mortality but also lead to significant morbidity as a result of malnutrition.

Etiology.

Rotavirus, astrovirus, adenovirus, and caliciviruses, such as the Norwalk agent, are the medically important pathogens of human viral gastroenteritis.

Rotaviruses cause disease in virtually all mammals and birds. The virus is a wheel-like, double-shelled icosahedron containing 11 segments of double-stranded RNA. The diameter of the particles by electron microscopy is approximately 80?nm. Rotaviruses are classified by group (A, B, C, D, E), subgroup (I or II), and serotype. Group A, which has no antigenic relationship to the other groups, includes the common human pathogens as well as a variety of animal viruses. Group B rotavirus is reported as a cause of severe disease in infants and adults in China but not elsewhere. Occasional human outbreaks of group C rotavirus are reported. The other groups are limited to animal strains. Rotavirus strains are species-specific and do not cause disease in heterologous hosts. Subgrouping of rotaviruses is determined by the antigenic structure of the inner capsid protein, VP6. Serotyping of rotaviruses, as determined by classic cross-neutralization serology, depends on the outer capsid glycoproteins, VP7 and VP4. The VP7 serotype is referred to as the G type (for glycoprotein). The VP4 serotype is referred to as the P type. Although both VP4 and VP7 can elicit neutralizing immunoglobulin (Ig) G antibodies, the relative role of these systemic

antibodies compared with mucosal IgA antibodies and cellular responses in

protective immunity remains unclear.

Astroviruses are the second most important agent of viral gastroenteritis in young children, with a high incidence in both the developing and the developed worlds. Astroviruses are positive-sense, single-stranded RNA viruses. They are small, approximately 30-nm diameter particles with a characteristic central five- or six-pointed star when viewed by electron microscopy. The capsid consists of three structural proteins. There are eight known human serotypes.

Enteric adenoviruses are another common cause of viral gastroenteritis in infants and children. Although many adenovirus serotypes exist and are found in stool, especially during and after typical upper respiratory tract infections (Chapter 240), only serotypes 40 and 41 cause gastroenteritis. These strains do not cause respiratory symptoms and are very difficult to grow in tissue culture. They are 80-nm diameter icosahedral viruses with a relatively complex single-stranded DNA genome.

Caliciviruses are small 27- to 35-nm viruses that are the most common cause of gastroenteritis outbreaks in older children and adults. They are positive-sense, single-stranded RNA viruses with a single structural protein. Variant but closely related caliciviruses have been named for locations of initial outbreaks: **Norwalk**, Snow Mountain, Montgomery County, Sapporo, and others. Caliciviruses also cause a rotavirus-like illness in young infants. Caliciviruses and astroviruses are sometimes referred to as small, round viruses on the basis of appearance on electron microscopy.

Several other viruses that may cause diarrheal disease in animals have been postulated but not well established as human gastroenteritis viruses. These include coronaviruses, toroviruses, and pestiviruses. Picobirnaviruses, another group of small 30-nm, double-stranded RNA viruses, have been reported to be found in 10% of patients with HIV-associated diarrhea.

Epidemiology.

Worldwide, rotavirus is estimated to cause more than 125 million cases of diarrhea annually in children younger than 5 yr of age. Of these, 18 million cases are considered at least moderately severe, with approximately 600,000 deaths per year. Rotavirus causes 3 million cases of diarrhea, 50,000 hospitalizations, and 20–40 deaths annually in the United States.

Rotavirus infection is most common in winter months in temperate climates. In the United States, the annual winter peak spreads from west to east (Fig. 242–1). Unlike other winter viruses such as influenza, this wave of increased incidence is not due to a single prevalent strain or serotype. Typically, several serotypes predominate in a given community for one or two seasons while nearby locations may harbor unrelated strains. Disease tends to be most severe in patients 3–24 mo of age, although 25% of the cases of severe disease occur after 2 yr of age, with serologic evidence of infection developing in virtually all children by 4–5 yr of age. Infants younger than 3 mo of age are relatively protected by transplacental antibody and possibly breast-feeding. Infections in neonates and in adults in close contact with infected children are generally asymptomatic. Some rotavirus strains have stably colonized newborn nurseries for years, infecting virtually all newborns without any overt illness.

Rotavirus and the other gastroenteritis viruses spread efficiently via a fecal-oral route, and outbreaks are common in children's hospitals and child-care centers. The virus is shed in stool at very high concentration before and for days after the clinical illness. Very few infectious virions are needed to cause disease in a susceptible host.

The epidemiology of astroviruses is not as thoroughly studied as rotavirus, but it is a common cause of mild to moderate watery winter diarrhea in children and infants and an uncommon pathogen in adults. Hospital outbreaks are common. Enteric adenovirus gastroenteritis occurs year-round, mostly in

Figure 242-1 Peak rotavirus activity by month in the United States for July 1996 to June 1997. This pattern is typical of the annual rotavirus activity each year. (From Centers for Disease Control and Prevention: Laboratory-based surveillance for rotavirus—United States, July 1996–June 1997. *MMWR* 1997;46:1092–4. A short animation showing rotavirus activity by week from July 1996–1997 is available online (ftp://ftp.cdc.gov/ pub/publications/mmwr/wk/rota9697.gif).

children younger than 2 yr. Nosocomial outbreaks occur but are less common than with rotavirus and astrovirus. Calicivirus is best known for causing large, explosive outbreaks among older children and adults, particularly in settings such as schools, cruise ships, and hospitals. Often a single food, such as shellfish or water used in food preparation, is identified as a source.

Pathogenesis.

Viruses that cause human diarrhea selectively infect and destroy villus tip cells in the small intestine. Biopsies of the small intestines show variable degrees of villus blunting and round cell infiltrate in the lamina propria. Pathologic changes may not correlate with the severity of clinical symptoms and usually resolve before the clinical resolution of diarrhea. The gastric mucosa is not affected despite the commonly used term “gastroenteritis,” although delayed gastric emptying has been documented during Norwalk virus infection.

In the small intestine, the upper villus enterocytes are differentiated cells, which have both digestive functions, such as hydrolysis of disaccharides, and absorptive functions, such as the transport of water and electrolytes via glucose and amino acid co-transporters. The crypt enterocytes are undifferentiated cells, which lack the brush border hydrolytic enzymes and are net secretors of water and electrolytes. Selective viral infection of intestinal villus tip cells thus leads to (1) an imbalance in the ratio of intestinal fluid absorption to secretion and (2) malabsorption of complex carbohydrates, particularly lactose. Most evidence supports the first mechanism as the more important factor in the genesis of viral diarrhea. It has been proposed that a rotavirus nonstructural protein may function as an enterotoxin.

In the normal host, extraintestinal infection is rare, although immunocompromised patients may experience hepatic and renal involvement. The increased vulnerability of infants (compared with older children and adults) to severe morbidity and mortality from gastroenteritis viruses may relate to a number of factors, including decreased intestinal reserve function, lack of specific immunity, and decreased nonspecific host defense mechanisms such as gastric acid and mucus. Viral enteritis greatly

enhances intestinal permeability to luminal macromolecules and has been postulated to increase the risk of food allergies.

Clinical Manifestations.

Rotavirus infection typically begins after an incubation period of less than 48?hr, with mild to moderate

---

fever and vomiting followed by the onset of frequent, watery stools. Vomiting and fever typically abate during the second day of illness, but diarrhea often continues for 5–7 days. The stool is without gross blood or white cells. Dehydration may develop and progress rapidly, particularly in infants. Malnourished children and children with underlying intestinal disease such as short-bowel syndrome are particularly likely to acquire severe rotavirus diarrhea. Rarely, immunodeficient children experience severe and prolonged illness. Although most newborns infected with rotavirus are asymptomatic, some outbreaks of necrotizing enterocolitis have been associated with the appearance of a new rotavirus strain in the affected nurseries.

The clinical course of astrovirus appears to be similar to that of rotavirus, with the notable exception that the disease tends to be milder, with less significant dehydration. Adenovirus enteritis tends to cause diarrhea of longer duration, often 10–14 days. The Norwalk virus has a short (12?hr) incubation period. Vomiting and nausea tend to predominate in illness associated with the Norwalk virus, and the duration is brief, usually 1–3 days of symptoms. The clinical and epidemiologic picture of Norwalk virus often closely resembles so-called food poisoning from preformed toxins such as *Staphylococcus aureus* and *Bacillus cereus*.

Diagnosis.

In most cases, a satisfactory diagnosis can be made on the basis of the clinical and epidemiologic features. Enzyme immunoassays, which offer approximately 90% specificity and sensitivity, are available for detection of group A rotavirus and enteric adenovirus in stool samples. More obscure cases can be studied by electron microscopy of stools, RNA electrophoresis, nucleic acid hybridization, and polymerase chain reaction assays. The diagnosis of viral gastroenteritis should always be questioned in patients with persistent high temperature, blood or white cells in the stool, or persistent severe or bilious vomiting (especially in the absence of diarrhea).

LABORATORY FINDINGS.

Isotonic dehydration with acidosis is the most common finding in children with severe viral enteritis. The stools are free of blood and leukocytes. Although the white blood cell count may be moderately elevated secondary to stress, the marked left shift seen with invasive bacterial enteritis is absent.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis includes other infectious causes of enteritis such as bacteria and protozoa. Occasionally, surgical conditions such as appendicitis, bowel obstruction, and intussusception may initially mimic viral gastroenteritis.

Treatment.

Avoiding and treating dehydration are the main goals in treatment of viral enteritis. A secondary goal is maintenance of the nutritional status of the patient.

There is no role for antiviral drug treatment of viral gastroenteritis. Controlled studies have shown no benefit from antiemetics or antidiarrheal drugs, and there is a significant risk of serious side effects. Antibiotics are similarly of no benefit. Immunoglobulins have been administered orally to both normal and immunodeficient patients with severe rotavirus gastroenteritis, but this treatment is currently considered experimental. Therapy with probiotic organisms such as *Lactobacillus* species has been shown to reduce somewhat the intensity and duration of illness.

SUPPORTIVE TREATMENT.

Rehydration can be accomplished in most patients via the oral route. Modern rehydration solutions containing appropriate quantities of sodium and glucose promote optimum absorption of fluid from the intestine (see Table 47.1). There is no evidence that a particular carbohydrate source (e.g., rice) or addition of amino acids improves the efficacy of these solutions for children with viral enteritis. Other clear liquids such as flat soda, fruit juice, and sports drinks are inappropriate for rehydration of young children with significant stool loss. Rehydration via the oral (or nasogastric) route should be done over 6–8?hr and feedings begun immediately thereafter. Providing the rehydration fluid at a slow, steady rate, typically 5?mL/min, reduces vomiting and improves the success of oral therapy. Rehydration solution should be continued as a supplement to make up for ongoing excessive stool losses. Initial intravenous fluids are required for the infant in shock or the occasional child with intractable vomiting.

After rehydration has been achieved, resumption of a normal diet for age has been shown to result in a more rapid recovery from viral gastroenteritis. Prolonged (>12?hr) administration of exclusive clear liquids or dilute formula is without clinical benefit and actually prolongs the duration of diarrhea. Breast-feeding should be continued even during rehydration. Selected infants may benefit from lactose-free feedings (such as soy formula or lactose-free cow's milk) for several days, although this is not necessary for most children. Hypocaloric diets low in protein and fat such as BRAT (**b**ananas, **r**ice, cereal, **a**pplesauce, and **t**oast) have not been shown to be superior to a regular diet.

Prognosis.

Most fatalities occur in infants with poor access to medical care and are attributed to dehydration. Children may be infected with rotavirus several times during their lives

but with decreasing severity of subsequent infections. After the initial natural infection, children have limited protection against any subsequent infection (38%) and diarrhea (77%) but have protection against severe diarrhea (87%).

Prevention.

Good hygiene reduces the transmission of viral gastroenteritis, but even in the most hygienic societies virtually all children become infected as a result of the efficiency of infection of the gastroenteritis viruses. Good handwashing and isolation procedures can help control nosocomial outbreaks. The role of breast-feeding in prevention or amelioration of rotavirus infection may be small given the variable protection observed in a number of studies.

VACCINE.

A rotavirus vaccine was licensed in 1998 for oral administration to infants at 2, 4, and 6 mo of age. The vaccine offered >80% protection against severe disease. In 1999, preliminary analysis of ongoing post-licensure surveillance of adverse events identified several cases of intussusception among recipients of rotavirus vaccine, usually occurring during the 1st wk after immunization and usually after the first dose. Use of the vaccine was suspended in July 1999 and the manufacturer has removed it from the market. Subsequent analysis has suggested that infants receiving the vaccine had an approximate 1 in 10,000 risk of developing intussusception. Several new rotavirus vaccine candidates are under development.

Chapter 243 - Human Papillomaviruses

Anna-Barbara Moscicki

Human papillomaviruses (HPVs) cause a variety of proliferative cutaneous and mucosal lesions, including common skin warts, benign and malignant ano-genital tract lesions, and life-threatening respiratory papillomas. Most HPV-related infections in children and adolescents who come to medical attention are benign.

Etiology.

The papillomaviruses are small (55?nm), DNA-containing viruses that are ubiquitous in nature, infecting most mammalian and many nonmammalian animal species. Strains are almost always species-specific. More than 100 different types of HPVs have been identified by sequence homology. The different HPV types typically cause disease in specific anatomic sites; about 30 of the HPV types have been identified from genital tract specimens.

The difficulty to propagate these pathogens in tissue culture has prevented the application of traditional virologic culture methods to their study and slowed progress in the field, but newer molecular techniques have spawned a dramatic increase in current understanding.

Epidemiology.

HPV infections of the skin are common, and most individuals are probably infected with one or more HPV types at some time. There are no animal reservoirs for HPV, and all transmission is presumably person-to-person. There is little evidence to suggest that HPV is transmitted by fomites. Common warts including palmar and plantar warts are frequently seen in children and adolescents, where they infect the hands and feet, common areas of frequent minor trauma.

Human papillomavirus is the most prevalent viral sexually transmitted infection in the United States. Although up to 70% of sexually active women eventually acquire HPV through sexual transmission, the infection is rare among preadolescent children. The greatest risk for HPV in sexually active adolescents is exposure to new sexual partners, underscoring the ease of transmission of this virus through sexual contact. As with many other genital pathogens, perinatal transmission to newborns also occurs but the transmission of genital types appears to be relatively inefficient.

The most common manifestation of HPV is latent infection defined by the detection of HPV DNA in the absence of any detectable HPV-associated lesion. Approximately 20% of sexually active adolescents have detectable HPV at any one point in time without detectable lesions. In contrast, external genital warts are much less common, occurring in <1% of adolescents. The most common clinically detected lesion in adolescent women is the cervical lesion termed **low-grade squamous intraepithelial lesion (LSIL)** (Table 243–1). This appears to occur in 25–50% of adolescents infected with HPV. LSILs are considered benign cellular changes associated with HPV infection. As with HPV DNA detection, most LSILs regress spontaneously and do not require any intervention or therapy. Less common, HPV can induce more severe cellular changes termed **high-grade squamous intraepithelial lesions (HSIL)**. Although HSILs are considered true precancerous lesions, these lesions rarely progress to invasive cancer. HSIL occurs in approximately 0.4–3% of sexually active women, whereas invasive cervical cancer occurs in less than 14 cases per 100,000 adult women. In true virginal populations, including children who are not sexually abused, rates of both clinical disease and HPV detection are very low to zero.

Some infants may acquire papillomaviruses during passage through an infected birth canal, leading to recurrent respiratory papillomatosis. Cases have been reported after cesarean section. The maximum incubation period for emergence of clinically apparent lesions (genital warts or laryngeal papillomas) after perinatally acquired infection is unknown, but appears to be around 6 mo of age. Genital warts appearing in later childhood often result from sexual abuse, with papillomavirus transmission during the abusive contact. Genital warts may represent a sexually transmitted disease even in some very young children. Their presence is cause to suspect that possibility. A child with genital warts should, therefore, be provided with a complete evaluation for possible abuse (Chapter 35.1), including the presence of other sexually transmitted diseases (Chapter 110).

Pathogenesis.

Initial infection of the cervix with HPV is thought to begin by viral invasion of the basal cells of the epithelium, which is enhanced by disruption of the epithelium caused by trauma or inflammation. It is thought that, at first, the virus remains relatively dormant, because the virus is present without any evidence of clinical disease. The life cycle of HPV is dependent on the differentiation program of keratinocytes. The pattern of HPV transcription varies throughout the epithelial layer as well as through different stages of disease (i.e., LSIL, HSIL, invasive cancer). Understanding of HPV transcription enhances understanding of its ability to behave as an oncovirus. Much of the research has focused on the early region proteins, E6 and E7. These proteins function as trans-activating factors that regulate cellular transformation. Complex interactions between E6 and E7 transcribed proteins and host proteins result in the perturbation of normal processes that regulate cellular DNA synthesis. The perturbations caused by E6 and E7 are primarily through disruption of the anti-oncoproteins, p53 and retinoblastoma protein (Rb), respectively, contributing to the development of anogenital cancers.

TABLE 243-1 -- **Bethesda System for Reporting Cervical/Vaginal Cytology**

Descriptive Diagnosis of Epithelial Cell Abnormalities	Equivalent Terminology
Squamous Cell	
Atypical squamous cells of undetermined significance (ASC-US)	Squamous atypia
Atypical squamous cells, cannot exclude HSIL (ASC-H)	
Low-grade squamous intraepithelial lesion (LSIL)	Mild dysplasia, condylomatous atypia, HPV-related changes, koilocytic atypia, cervical epithelial neoplasia (CIN) 1
High-grade squamous intraepithelial lesion (HSIL)	Moderate dysplasia, CIN 2, severe dysplasia, CIN 3, carcinoma in situ
Glandular Cell	
Endometrial cells, cytologically benign, in a postmenopausal woman	
Atypical glandular cells of undetermined significance	
Endocervical adenocarcinoma	
Endometrial adenocarcinoma	
Extrauterine adenocarcinoma	
Adenocarcinoma, not otherwise specified	

Evidence of productive viral infection occurs in benign lesions such as external genital warts and LSIL with the abundant expression of viral capsid proteins in the superficial keratinocytes. The appearance of the HPV-associated koilocyte is due to the expression of E4, a structural protein that causes collapse of the cytoskeleton. Although not as abundant, mild expression of E6 and E7 proteins results in cell proliferation seen in the basal cell layer of LSIL. Most researchers conclude that LSIL is a manifestation of active viral replication and protein expression. However, as the lesions advance in grade, expression of those products important in the process of cell transformation, such as E6 and E7, now predominate, rather than structural proteins, resulting in the chromosomal abnormalities and aneuploidy characteristic of the higher grade lesions.

Cutaneous lesions (e.g., common warts) are not associated with malignant HPV types nor do they have any malignant potential except in the rare skin disorder epidermodysplasia verruciformis. Genital lesions caused by HPV may be broadly grouped into those with little to no malignant potential (i.e., low risk) and those with greater malignant potential (i.e., high risk). Low-risk HPV types 6 and 11 are most commonly found in genital warts and are rarely to never found isolated in malignant lesions. Whereas high-risk types, including types 16 and 18 but also 31, 33, 35, 45, and 56, are commonly found in SIL and invasive anogenital cancers. These types are also most commonly found in women without lesions as well. Lesions may also be infected simultaneously with multiple HPV types. Almost all latent infections with low-risk types spontaneously resolve over time. Genital and common warts in general resolve without therapy but may take years. Although most latent high-risk type infections resolve as well, they are more likely than low-risk types to persist. Persistent high risk type infections are associated with increased risk of developing HSIL and invasive cancer.

Most infants with recognized genital warts are infected with the low-risk types. In contrast, children with a history of sexual abuse have a picture more like adult genital warts with mixed low- and high-risk types. There have been only rare reports of HPV-associated genital malignancies occurring in preadolescent children and adolescents. On the other hand, HSIL does occur in sexually active adolescents. There is also a concern that younger age of sexual debut has contributed to the increase of invasive cervical cancer seen in women <50 yr in the United States. Prevention of adolescent sexually transmitted diseases, including HPV infections, is a major goal of current public health initiatives.

Clinical Manifestations.

The clinical findings depend on the site of epithelial infection.

SKIN LESIONS.

The typical HPV-induced lesions of the skin are proliferative, papular, and hyperkeratotic. Common warts are raised circinate lesions with a keratinized surface. Plantar and palmar warts are the results of pressure and are therefore practically flat. Multiple warts are common and may create a mosaic pattern. Flat warts appear as small, 1–5?mm flat flesh-colored papules.

GENITAL WARTS.

Genital warts may be found throughout the perineum around the anus, vagina, and urethra, as well as the cervical, intravaginal, and intra-anal areas. Intra-anal warts occur predominantly in patients who have had receptive anal intercourse, as contrasted with perianal warts that may occur in men and women without a history of anal sex. Although rare, lesions caused by genital genotypes can also be found on other mucosal surfaces such as conjunctivae, gingiva, and nasal mucosa. They may be single or multiple lesions and are frequently found in multiple anatomic sites. External genital warts can be flat, dome-shaped, keratotic, pedunculated, and cauliflower-shaped; they may occur singly, in clusters, or as plaques. On mucosal epithelium, the lesions are softer. Depending on the size and anatomic location, lesions may be pruritic and painful, cause burning with urination, be friable and bleed, or become superinfected. Children may be very disturbed by the development of genital lesions. Other rarer lesions caused by HPV of the external genital area

include Bowen disease, Bowenoid papulosis, squamous cell carcinomas, Buschke-Löwenstein tumors, and vulvar intraepithelial neoplasias (VIN).

Squamous intraepithelial lesions detected by cytology are usually invisible to the naked eye and require the aid of colposcopic magnification and acetic acid. With aid, the lesions appear white and show evidence of neovascularity. SIL can occur on the cervix, vagina, vulva, and intra-anus. Invasive cancers tend to be more exophytic with aberrant appearing vasculature. These lesions are rarely found in non-sexually active individuals.

LARYNGEAL PAPILLOMATOSIS.

The median age of onset of recurrent laryngeal papillomatosis is 3 yr of age. Children present with hoarseness or, in infants, an altered cry and sometimes stridor. Rapid growth of respiratory papillomas can occlude the upper airway, causing respiratory compromise. These lesions may recur within weeks of removal, requiring frequent surgery. The lesions do not become malignant.

Diagnosis.

The diagnosis of external genital warts and common warts may be reliably determined by visual inspection of a lesion by an experienced observer and does not require additional tests for confirmation. A biopsy should be considered if the diagnosis is uncertain, the lesions do not respond to therapy, or the lesions worsen during therapy.

The diagnosis for cervical SIL or cancer is initiated by screening with cytology. The most recent recommended terminology for cytologic evaluation is listed in Table 243–1 . Although the purpose of screening is to identify the significant precancer HSIL, the majority of confirmed HSIL is found in women who were referred for ASC-US or LSIL. Therefore, cytologic evaluation of cervical cells is a screening test and not confirmatory. Current recommendations for triage to colposcopy and biopsy for women with ASC-US is to repeat a Papanicolaou smear in 4–6 mo and refer only those women with persistent abnormal cytology. Because of the high rate of LSIL regression in adolescents and young women, clinicians may also choose to repeat cytologic study with LSIL within 6–12 mo for young women diagnosed with LSIL. For persistent LSIL, referral to colposcopy can be deferred up to 24 months. However, close follow-up of these women is critical because 17% of young women with LSIL have HSIL confirmed on histology. All women with cytologically identified HSIL should be referred for colposcopy and biopsy.

The majority of recommendations agree that cytologic screening should be initiated after the onset of sexual activity. Although the recommended interval between first sexual intercourse and first annual Papanicolaou smear is debatable, evidence suggests that screening may begin within the first 3 yr after intercourse. Screening earlier than 3 yr is more likely to result in overreferrals for colposcopy because most lesions in this group are likely to be LSIL. Upper age limit for screening is 18–21 yr in order to capture those women who have not revealed their sexual activity.

There are no commercially available serologic tests to assist in the diagnosis of HPV infection. During the past decade, very sensitive tests for the presence of HPV DNA, RNA, and proteins have been developed. These tests are becoming generally available, although they are not required for the diagnosis of external genital warts or related conditions. Recent application of HPV DNA testing assists in the triage of atypical cells of undetermined significance. Because half of patients with ASC-US do not require any further evaluation, HPV testing can assist in triage. Women with ASC-US and a positive HPV test for high-risk types are more likely to have significant underlying disease (i.e., HSIL) than women with a negative HPV test, and they may benefit from referral for colposcopy rather than waiting another 6 mo for repeat cytology. Another indication for HPV testing is follow-up of LSIL. At 12 mo follow-up of LSIL, a positive test for high-risk HPV types indicates referral for colposcopy.

DIFFERENTIAL DIAGNOSIS.

A number of other conditions should be considered including condyloma latum, seborrheic keratoses, dysplastic and benign nevi, molluscum contagiosum, pearly penile papules, and neoplasms. Condyloma latum is due to secondary syphilis and can be diagnosed using dark-field microscopy and standard serologic tests for syphilis. Seborrheic keratoses are common, localized hyperpigmented lesions that are rarely associated with malignancy. Molluscum contagiosum is caused by a poxvirus, is highly infectious, and is often umbilicated. Pearly penile papules occur at the penile corona and are normal variants that require no treatment.

Treatment.

Most common warts eventually resolve spontaneously. Symptomatic lesions should be removed. Removal includes a variety of self-applied therapies including salicylic acid preparations and provider-applied therapies (e.g., cryotherapy, laser therapy, and electrosurgery). Genital warts of children and adolescents are benign and usually remit, but only over an extended period of time. It is recommended that genital lesions be treated if the patient or the parent requests therapy. Similar to common warts, treatment is categorized into self-applied and provider applied. No one therapy has been shown to be more efficacious than any other. Provider-applied therapies include surgical treatments (e.g., electrosurgery, surgical excision, and laser surgery) and office-based treatment (e.g., cryotherapy with liquid nitrogen or a cryoprobe, podophyllin resin 10–25%, and bi- and tri-chloroacetic acid). Podophyllin resins have lost favor to other methods because of the variability in preparations. Intralesional, but not systemic, interferon is no more effective than other therapies and is associated with significant adverse effects. This therapy is reserved for treatment of recalcitrant cases.

Many therapies are painful, and children should not undergo painful genital treatments unless adequate pain control is provided. Parents and patients should not be expected to apply painful therapies themselves. In adolescents and adults, recommended patient-applied treatment regimens for external genital warts include topical podofilox and imiquimod. Podofilox 0.5% solution (using a cotton swab) or gel (using a finger) is applied to visible warts in a cycle of applications twice a day for 3 days followed by 4 days of no therapy, repeated for up to a total of four cycles.

Imiquimod 5% cream is applied at bedtime, three times a week, every other day, for up to 16 wk; the treated area should be washed with mild soap and water 6–10?hr after treatment. Neither podofilox nor imiquimod is recommended during pregnancy. For any of the nonsurgical treatments, prescription is contraindicated when there is any history of hypersensitivity to any product constituents.

If exposure as a result of sexual abuse is suspected or known, the clinician should ensure that the child's safety has been achieved and is maintained.

Ablative treatment including cryotherapy, loop electrosurgical excisional procedure, and laser therapy for HSIL is universally recommended. LSIL can be observed for up to 24 mo before treatment is offered.

Complications.

The presence of these lesions in the genital area may be a cause of profound embarrassment to a child or parent. Complications of therapy are uncommon; chronic pain (vulvodynia) or hypoesthesia may occur at the treatment site. Lesions may heal with hypopigmentation or hyperpigmentation and less commonly with depressed or hypertrophic scars. Surgical therapies can lead to infection and scarring. Repeated procedures of the cervix may lead to problems with infertility.

Numerous epidemiologic studies of adults, but not children, have demonstrated that papillomavirus infection, especially with types 16 and 18, is a strong risk factor for precancerous lesions and cancer. Respiratory papillomas also may become malignant, especially if they have been treated with radiation.

Prognosis.

With all forms of therapy, lesions very commonly recur, and approximately one half of children require a second or third treatment. This appears to be especially true for respiratory papillomatosis. Patients and parents should be warned of this likelihood. Combination therapy does not improve response but may increase complications. Prognosis of cervical disease is better, with 85–90% cure rates after a single treatment. Recalcitrant disease should prompt an evaluation and is common in immunocompromised individuals, specifically men and women infected with HIV.

Prevention.

The only means to prevent infection is to avoid direct contact with lesions. Condoms have not been shown universally to prevent HPV transmission, although condoms prevent other sexually transmitted infections, which are risk factors associated with SIL development. In addition, avoiding smoking cigarettes is important in preventing cervical cancer.

Chapter 244 - Arboviral Encephalitis in North America

Scott B. Halstead

The *ar*thropod-*bo*rne (*arbo*virus) viral encephalitides are a group of clinically similar severe neurologic infections caused by several different viruses. They are transmitted by mosquitoes during warm weather and are incurred by outdoor exposure in overlapping regions across most of the United States and much of southern Canada.

Etiology.

The principal causes of the arthropod-borne encephalitides of North America include the newly introduced West Nile encephalitis (WNE), St. Louis encephalitides (SLE), the complex of viruses included in the California (CE) encephalitis group of viruses, and, less frequently, western equine encephalitis (WEE), eastern equine encephalitis (EEE), and Colorado tick fever. The etiologic agents belong to different viral taxa: alphaviruses of the family Togaviridae (EEE and WEE), Flaviviridae (WNE, SLE), the California complex of the Bunyaviridae (CE), and Reoviridae (Colorado tick fever virus). Alphaviruses are 69-nm enveloped positive-strand RNA viruses that evolved from a common Venezuelan equine encephalitis-like viral ancestor in the Western Hemisphere. Flaviviruses are 40- to 50-nm enveloped positive-strand RNA viruses evolved from a common ancestor, globally distributed, and responsible for many important human viral diseases. The California serogroup, one of 16 Bunyavirus

groups, are 75- to 115-nm enveloped viruses possessing a three-segment negative-strand RNA genome. Reoviruses are 60- to 80-nm double-stranded RNA viruses.

Epidemiology.

Viral encephalitis cases and outbreaks were only recognized during the 20th century, when human population densities across the United States became relatively high, public health disease reporting systems were maturing, and laboratories were able to discriminate viral from bacterial infections. From the mid-19th century, epizootics of equine encephalitis were observed in the United States. In 1931, WEE was isolated from horse cases in the Central Valley of California. In 1938, the same virus was recovered from the central nervous system from fatal human cases. In the summer of 1932, an epidemic of human encephalitis, first regarded as Von Economo's disease, was recognized in Paris, IL. The next year, more than 1,000 cases were reported from St. Louis County, and several SLE viruses were isolated. In 1933, EEE virus was isolated from a horse epizootic, which occurred in Virginia, Maryland, Delaware, and New Jersey. The same virus was isolated from human cases in 1938. The first CE virus, now called La Crosse virus, was isolated in 1960 from a fatal case of encephalitis in a 4-yr-old girl in rural Wisconsin. Colorado tick fever was first described as a nosologic entity in 1930.

EASTERN EQUINE ENCEPHALITIS.

In the United States, EEE is a very low incidence disease, with a median of three cases occurring annually in the Atlantic and Gulf states (Fig. 244–1). Transmission occurs often in focal endemic areas of the coast of Massachusetts, the six southern counties of New Jersey, and northeastern Florida. In North America, the virus is maintained in freshwater swamps in a zoonotic cycle involving *Culiseta melanura* and birds. Various other mosquito species obtain viremic

Figure 244-1 The incidence of reported cases of Eastern equine encephalitis (*A*), Western equine encephalitis (*B*), St. Louis encephalitis (*C*), and California encephalitis (*D*) reported to the Centers for Disease Control and Prevention in 1997.

meals from birds and transmit the virus to horses and humans. Virus activity varies markedly from year to year in response to still unknown ecologic factors. Most infections in birds are silent, but infections in pheasants are often fatal, and epizootics in these species are used as sentinels for periods of increased viral activity. Cases have been recognized on Caribbean islands. The case to infection ratio is lowest in children (1:8) and somewhat higher in adults (1:29).

WESTERN EQUINE ENCEPHALITIS.

Infections occur principally in the United States and Canada west of the Mississippi River (see Fig. 244–1) mainly in rural areas where water impoundments, irrigated farmland, and naturally flooded land provide breeding sites for *Culex tarsalis*. The virus is transmitted in a cycle involving mosquitoes, birds, and other vertebrate hosts. Humans and horses are susceptible to encephalitis. The case to infection ratio varies by age, having been estimated at 1:58 in children younger than 4 yr and 1:1,150 in adults. Infections are most severe at the extremes of life; one third of cases occur in children younger than 1 yr. Recurrent human epidemics have been reported from the

Yakima Valley in Washington State and the Central Valley of California; the largest outbreak on record—3,400 cases—occurred in Minnesota, North and South Dakota, Nebraska, and Montana and Alberta, Manitoba, and Saskatchewan, Canada. Epizootics in horses precede human epidemics by several weeks. For the past 20 years, possibly as a result of successful mosquito abatement, few cases of WEE have been reported.

ST. LOUIS ENCEPHALITIS.

Cases are reported from nearly all states; the highest attack rates occur in the Gulf and central states (see Fig. 244–1). Epidemics frequently occur in urban and suburban areas; the largest, in 1975, involved 1,800 persons living in Houston, Chicago, Memphis, and Denver. Cases often cluster in areas where there is ground water or septic systems, which support mosquito breeding. The principal vectors are *Culex pipiens* and *C. quinquefasciatus* in the central Gulf states, *C. nigripalpus* in Florida, and *C. tarsalis* in California. SLE virus is maintained in nature in a bird-mosquito cycle. Viral amplification occurs in bird species abundant in residential areas (e.g., sparrows, blue jays, and doves). Virus is transmitted in the late summer and early fall. The case to infection ratio may be as high as 1:300. Age-specific attack rates are lowest in children and highest in individuals older than 60 yr.

WEST NILE ENCEPHALITIS.

During the past decade, WNE virus has been implicated as the cause of sporadic summer time human cases of encephalitis and meningitis in Israel, India, Pakistan, Romania, and Russia. West Nile virus belonging to lineage I was introduced into the United States in 1999. It was initially isolated from a cluster of patients in Queens, NY, in September 1999 following an earlier die-off of crows and exotic birds at the Bronx Zoo. All American WNE viruses are genetically similar and are related to a virus recovered from a goose in Israel in 1998. WNE virus survives in a broad enzootic cycle in the United States and within 4 yr has spread to most states east of the Rocky Mountains plus California. A nationwide epidemic, particularly in the central states, occurred in 2002. Throughout its range, the virus is maintained in nature by transmission between mosquitoes of the *Culex* genus and various species of birds. In the United States, human infections are largely acquired from *Culex pipiens*. Horses are the nonavian vertebrates most likely to exhibit disease with WNE infection. In New York in 1999, 25 equine cases were observed.

Disease occurs predominantly in individuals over the age of 50 yr.

LA CROSSE/CALIFORNIA ENCEPHALITIS.

La Crosse viral infections are endemic in the United States, occurring annually from July to September, principally in the north central and central states (see Fig. 244–1). Infections occur in peridomestic environments as the result of bites from *Aedes triseriatus* mosquitoes, which often breed in tree holes. The virus is maintained vertically in nature by transovarial transmission and can be spread between mosquitoes by copulation and amplified in mosquito populations by viremic infections in various vertebrate hosts. Amplifying hosts include chipmunks, squirrels, foxes, and woodchucks. A case:infection ratio of 1:22–300 has been surmised. La Crosse encephalitis is principally a disease of children, who may constitute up to 75% of cases.

COLORADO TICK FEVER.

Colorado tick fever virus is transmitted by the wood tick *Dermacentor andersoni,* which inhabits high-elevation areas of states extending from the central plains to the Pacific coast. The tick is infected with the virus at the larval stage and remains infected for life. Squirrels and chipmunks serve as primary reservoirs. Human infections typically occur in hikers and campers in indigenous areas during the spring and early summer.

Clinical Manifestations.

With the exception of EEE, these arboviruses produce similar symptoms of encephalitis.

EASTERN EQUINE ENCEPHALITIS.

Infections result in a fulminant encephalitis with a rapid progression to coma and death in one third of cases. In infants and children, abrupt onset of fever, irritability, and headache are followed by lethargy, confusion, seizures, and coma. High temperature, bulging fontanel, stiff neck, and generalized flaccid or spastic paralysis are observed. There may be a brief prodrome of fever, headache, and dizziness. Unlike most other viral encephalitides, the peripheral white blood cell count usually demonstrates a marked leukocytosis, and the cerebrospinal fluid may show marked pleocytosis. Pathologic changes are found in the cortical and gray matter, with viral antigens localized to neurons. There is necrosis of neurons, neutrophilic infiltration, and perivascular cuffing by lymphocytes.

WESTERN EQUINE ENCEPHALITIS.

There may be a prodrome with symptoms of an upper respiratory tract infection. The onset is usually sudden with chills, fever, dizziness, drowsiness, increasing headache, malaise, nausea and vomiting, stiff neck, and disorientation. Infants typically present with the sudden cessation of feeding, fussiness, fever, and protracted vomiting. Convulsions and lethargy develop rapidly. On physical examination, patients are somnolent, exhibit meningeal signs, and have generalized motor weakness and reduced deep tendon reflexes. In infants, a bulging fontanel, spastic paralysis, and generalized convulsions may be observed. On pathologic examination, disseminated small focal abscesses, small focal hemorrhages, and patchy areas of demyelination are distinctive.

ST. LOUIS ENCEPHALITIS.

Clinical manifestations vary from a mild flulike illness to fatal encephalitis. There may be a prodrome of nonspecific symptoms with subtle changes in coordination or mentation of several days to 1 wk in duration. Early signs and symptoms include fever, photophobia, headache, malaise, nausea, vomiting, and neck stiffness. About one half of patients exhibit abrupt onset of weakness, incoordination, disturbed sensorium, restlessness, confusion, lethargy, and delirium or coma. The peripheral

white blood cell count is modestly elevated, with 100–200 cells/mm^3 found in the cerebrospinal fluid. On autopsy, the brain shows scattered foci of neuronal damage and perivascular inflammation.

WEST NILE ENCEPHALITIS.

In the early literature, WNE in adults was described as a dengue-like syndrome. Disease in the United States has been accompanied by prolonged lymphopenia and the syndromes of encephalitis or meningitis.

CALIFORNIA ENCEPHALITIS.

The clinical spectrum includes a mild febrile illness, aseptic meningitis, and fatal encephalitis. Children typically present with a prodrome of 2–3 days with fever, headache, malaise, and vomiting. The disease evolves with clouding of the sensorium, lethargy, and, in severe cases, focal or generalized seizures. On physical examination, children are lethargic but not disoriented. Focal neurologic signs, including weakness, aphasia, and focal or generalized seizures, have

been reported in 16–25% of cases. Cerebrospinal fluid shows low to moderate leukocyte counts. On autopsy, the brain shows focal areas of neuronal degeneration, inflammation, and perivascular cuffing.

COLORADO TICK FEVER.

The illness begins with the abrupt onset of a flulike illness, including high temperature, malaise, arthralgias and myalgia, vomiting, headache, and decreased sensorium. Rash is uncommon. The symptoms rapidly disappear after 3 days of illness. However, in approximately one half of patients, a second, identical episode recurs 24–72?hr after the first, producing the typical “saddle-back” temperature curve of Colorado tick fever. Complications, including encephalitis or meningoencephalitis or a bleeding diathesis, develop in 3–7% of infected persons and may be more common in children younger than 12 yr.

Diagnosis.

The etiologic diagnosis of a specific arboviral infection is established by testing an acute-phase serum =5 days after onset of illness for the presence of virus-specific immunoglobulin (Ig) M antibodies using an indirect immunofluorescence test or an enzyme-linked immunosorbent assay (ELISA) IgM-capture test. Alternatively, acute and convalescent sera can be tested for a fourfold or greater increase in ELISA, hemagglutination inhibition, or neutralizing IgG antibody titers. The diagnosis may also be established by isolation in cell cultures of virus in brain tissue, obtained by brain biopsy or at autopsy, or by identification of viral RNA reverse transcriptase/polymerase chain reactions.

The diagnosis of encephalitis may be aided by CT or MRI and by electroencephalography. Focal seizures or focal findings on CT or MRI or electroencephalogram should suggest the possibility of herpes simplex encephalitis, which should be treated with acyclovir (Chapter 231).

Treatment.

There is no specific treatment for arboviral encephalitides. The treatment of acute arboviral encephalitis is intensive supportive care (Chapter 57), including control of seizures (Chapter 586).

Prognosis.

With the exception of EEE, the arboviral encephalitides are self-limited and resolve without residua in most, but not all, patients.

EASTERN EQUINE ENCEPHALITIS.

The prognosis is better for patients with a prolonged prodrome; the occurrence of convulsions conveys a poor prognosis. Patient fatality rates are 33–75% and are highest in the elderly. Residual neurologic defects are common, especially in children.

WESTERN EQUINE ENCEPHALITIS.

Patient fatality rates are 3–9%, and are highest in the elderly. Major neurologic sequelae have been reported in up to 13% of cases and may be as high as 30% in infants. Parkinsonian syndrome has been reported as a residual in adult survivors.

ST. LOUIS ENCEPHALITIS.

The principal risk factor for fatal outcome is advanced age, with patient fatality rates being as high as 80% in early outbreaks. In children, mortality rates are 2–5%. In adults, underlying hypertensive cardiovascular disease has been a risk factor for fatal outcome. Recovery from SLE is usually complete, but serious neurologic sequelae have been reported to be as high as 10% in children.

WEST NILE ENCEPHALITIS.

Cases and deaths occurred mainly in the elderly, although serologic surveys in 1999 and 2000 showed evidence that 2.6% and 1% of the population in focal areas of New York City were infected, respectively. The mortality rate was approximately 10%; in 1999, there were 7 fatalities among 62 cases; in 2002, 263 deaths among 4,007 cases.

CALIFORNIA ENCEPHALITIS.

Recovery from CE is usually complete. The case fatality rate is about 1%.

COLORADO TICK FEVER.

Recovery from Colorado tick fever is usually complete. Three deaths have been reported, all in persons with hemorrhagic signs.

Prevention.

A killed EEE vaccine is available for horses, and an experimental killed vaccine is administered to human laboratory workers who handle EEE virus. Flocks of sentinel chickens or pheasants have been stationed at various locations along the Atlantic coast during the late summer or early fall to obtain early warning of increased transmission of EEE virus.

No human vaccine is available for the other arboviral encephalitides, although WNE vaccines are being developed. Extensive water management and mosquito abatement programs in California have reduced transmission of WEE and the incidence of human infections. Urban WNE and SLE outbreaks in the Eastern United States, Texas, and the Midwest have been controlled by the application of ultra low-volume adulticide chemicals applied from trucks or low-flying aircraft.

Because infections in children may occur as the result of summer daytime mosquito biting in residential areas, sealing mosquito breeding sites, using insect repellents, and instructing children to play in open, sunny areas away from forest fringe may help prevent disease.

Chapter 245 - Arboviral Encephalitis Outside North America

Scott B. Halstead

The principal causes of arboviral encephalitides outside North America are Venezuelan equine encephalitis (VEE) virus, Japanese encephalitis (JE) virus, tick-borne encephalitis (TBE), and West Nile (WN) virus (see Chapter 244) (Table 245–1).

245.1 Venezuelan Equine Encephalitis

The VEE virus was isolated from an epizootic in Venezuelan horses in 1938. Human cases were first identified in 1943. Hundreds of thousands of equine and human cases have occurred over the past 70 yr. During 1971, epizootics moved through Central America and Mexico to southern Texas. After 2 decades of quiescence, epizootic disease emerged again in Venezuela and Colombia in 1995.

TABLE 245.1-1 -- Vectors and Geographic Distribution of Arboviral Encephalitis Outside North America

Genus	Virus and Disease	Vector	Geographic Distribution
Flavivirus	Japanese encephalitis	*Culex tritaeniorhynchus*	Asia/Japan to Sri Lanka
Flavivirus	Murray Valley encephalitis	*Culex annulirostris*	Eastern Australia
Flavivirus	Rocio	*Psorophora* or *Aedes*	Sao Paulo, Brazil
Flavivirus	West Nile	*Culex* and others	Europe to Australia
Flavivirus	Tick-borne encephalitis	*Ixodes ricinus* *I. persulcatus*	Europe Russia
Togavirus	Venezuelan equine encephalitis	*Culex* and others	Northern South America

Etiology.

VEE is an alphavirus of the genus Togaviridae. VEE circulates in nature in six subtypes. Types I and III viruses have multiple antigenic variants. Types IAB and IC have caused epizootics and human epidemics.

Epidemiology.

The majority of epizootics resulting from types IAB and IC have occurred in Venezuela and Colombia. The virus resides in ill-defined sylvatic reservoirs in the South American rain forests. Known hosts include rodents and aquatic birds with transmission by *Culex melaconion* species. Vectors for horse-to-horse and horse-to-human transmission include *Aedes taeniorhynchus* and *Psorophora confinnis*. Epizootics move rapidly, up to several miles per day. Human cases are proportional to and follow epizootic occurrences. Viremia levels in human blood are high enough to infect mosquitoes. Because virus can be recovered from human pharyngeal swabs, and household attack rates are often as high as 50%, it is widely believed that person-to-person transmission occurs, although direct evidence is lacking. Types II–VI viruses are restricted to relatively small foci; each has a unique vector-host relationship and rarely results in human infections.

Clinical Manifestations.

The incubation period is 2–5 days followed by the abrupt onset of fever, chills, headache, sore throat, myalgia, malaise, prostration, photophobia, nausea, vomiting, and diarrhea. In 5–10% of cases, there is a biphasic illness; the second phase is heralded by seizures, projectile vomiting, ataxia, confusion, agitation, and mild disturbances in consciousness. On physical examination, there is cervical lymphadenopathy and conjunctival suffusion. Cases of meningoencephalitis may demonstrate cranial nerve palsy, motor weakness, paralysis, seizures, and coma. Microscopic examination of tissues reveals inflammatory infiltrates in lymph nodes, spleen, lung, liver, and brain. Lymph nodes show cellular depletion, necrosis of germinal centers, and lymphophagocytosis. The liver shows patchy hepatocellular degeneration, the lungs demonstrate a diffuse interstitial pneumonia with intra-alveolar hemorrhages, and the brain shows patchy cellular infiltrates.

Diagnosis.

The etiologic diagnosis of VEE is established by testing an acute-phase serum collected early in the illness for the presence of virus-specific immunoglobulin (Ig) M

antibodies or, alternatively, demonstrating a fourfold or greater increase in IgG antibody titers by testing paired acute and convalescent sera. The virus can also be identified by polymerase chain reaction (PCR).

Treatment.

There is no specific treatment for VEE. The treatment is intensive supportive care (Chapter 57), including control of seizures (Chapter 586).

Prognosis.

In patients with meningoencephalitis, the fatality rate ranges from 10–25%. Sequelae include nervousness, forgetfulness, recurrent headache, and easy fatigability.

Prevention.

Several veterinary vaccines are available to protect equines. VEE virus is highly infectious in laboratory settings, and BL-3 containment should be used. An experimental vaccine is available for use in laboratory workers.

245.2 Japanese Encephalitis

Epidemics of encephalitis were reported in Japan from the late 1800s. The JE virus was first isolated by Japanese workers by intracerebral inoculation of monkeys in 1934 and subsequently in mice in 1936. The virus was initially called Japanese B encephalitis to distinguish it from an unusual epidemic of von Economo (type A) encephalitis that occurred in Japan in the 1920s.

Etiology.

JE virus is a positive-sense single-stranded RNA virus and a member of the family Flaviviridae.

Epidemiology.

JE is a mosquito-borne viral disease of humans as well as horses, swine, and other domestic animals that causes human infections and acute disease in a vast area of Asia, northern Japan, Korea, China, Taiwan, Philippines, and the Indonesian archipelago and from Indochina through the Indian subcontinent. *Culex tritaeniorhynchus summarosus*, a nighttime-biting mosquito that feeds preferentially on large domestic animals and birds but only infrequently on humans, is the principal vector of zoonotic and human JE in northern Asia. A more complex ecology prevails in southern Asia. From Taiwan to India, *C. tritaeniorhynchus* and members of the closely related *Culex vishnui* group are vectors. Before the introduction of JE vaccine, summer outbreaks of JE occurred regularly in Japan, Korea, China, Okinawa, and Taiwan. Over the past decade, there has been a pattern of steadily enlarging recurrent seasonal outbreaks in Vietnam, Thailand, Nepal, and India, with small outbreaks in the Philippines, Indonesia, and the northern tip of Queensland, Australia. Seasonal rains are accompanied by increases in mosquito populations and increased transmission. Pigs serve as amplifying host.

The annual incidence in endemic areas ranges from 1–10/ 10,000 population. Children younger than 15 yr are principally affected, with nearly universal exposure by adulthood. The case to infection ratio for JE virus has been variously estimated at 1:25–1:1,000. Higher ratios have been estimated for populations indigenous to enzootic areas. JE occurs in travelers visiting Asia; therefore, a travel history in the diagnosis of encephalitis is critical.

Clinical Manifestations.

After a 4–14 day incubation period, cases typically progress through four stages: prodromal illness (2–3 days), acute stage (3–4 days), subacute stage (7–10 days), and convalescence (4–7 wk). Onset may be characterized by abrupt onset of fever, headache, respiratory symptoms, anorexia, nausea, abdominal pain, vomiting, and sensory changes, including psychotic episodes. Grand mal seizures are seen in 10–24% of children; parkinsonian-like nonintention tremor and cogwheel rigidity are seen less frequently. Particularly characteristic are rapidly changing central nervous system signs (e.g., hyperreflexia followed by hyporeflexia or plantar responses that change). The sensory status of the patient may vary from confusion, disorientation, delirium, or somnolence, progressing to coma. There is usually a mild pleocytosis (100–1,000 leukocytes/mm^3) in the cerebrospinal fluid, initially polymorphonuclear but in a few days predominantly lymphocytic. Albuminuria

---

is common. Fatal cases usually progress rapidly to coma, and the patient dies within 10 days.

Diagnosis.

JE should be suspected in patients reporting exposure to night-biting mosquitoes in endemic areas during the transmission season. The etiologic diagnosis of JE is established by testing an acute-phase serum collected early in the illness for the presence of virus-specific IgM antibodies or, alternatively, demonstrating a fourfold or greater increase in IgG antibody titers by testing paired acute and convalescent sera. The virus can also be identified by PCR.

Treatment.

There is no specific treatment for JE. The treatment is intensive supportive care (Chapter 57), including control of seizures (Chapter 586).

Prognosis.

Patient fatality rates are 24–42% and are highest in children aged 5–9 yr and in persons older than 65 yr. The frequency of sequelae is 5–70% and is directly related to age of the patient and to the severity of disease. Sequelae are most common in

patients younger than 10 yr at the onset of disease. The more common sequelae are mental deterioration, severe emotional instability, personality changes, motor abnormalities, and speech disturbances.

Prevention.

Travelers to endemic countries staying =1 mo in rural areas of the endemic region during the expected period of seasonal transmission, or those traveling in areas experiencing endemic transmission, should receive JE vaccine. The JE vaccine is given in a 3-dose series (0.5?mL for 1–3 yr of age; 1?mL for >3 yr of age) subcutaneously; the first two doses are given 1 wk apart and the third dose 30 days later. Booster doses are given every 2 yr while risk of exposure continues. Reactions to vaccination, including headache, malaise, myalgia, tenderness, redness, and swelling, occur in about 20% of vaccines. Serious generalized urticaria, facial angioedema, and respiratory distress have been observed in adults. Because vaccine is prepared in mouse brain, surveillance should be maintained for central nervous system disease after JE vaccination. In humans, prior dengue virus infection provides partial protection from clinical JE.

Personal measures should be taken to reduce exposure to mosquito bites, especially for short-term residents in endemic areas. This consists of avoiding evening outdoor exposure, using insect repellents, covering the body with clothing, and using bed nets or house screening.

Commercial pesticides, widely used by rice farmers in Asia, are effective in reducing populations of *C. tritaeniorhynchus*. Fenthion, fenitrothion, and phenthoate are effectively adulticidal and larvicidal. Insecticides may be applied from portable sprayers or from helicopters or light aircraft.

245.3 Tick-Borne Encephalitis

TBE was identified by Russian scientists in 1937 and was subsequently shown to be widespread in Europe, where it was identified as the cause of milk-borne encephalitis.

Etiology.

TBE virus is a positive-sense, single-stranded RNA virus and a member of the family Flaviviridae.

Epidemiology.

Tick-borne encephalitis refers to neurotropic tick-transmitted flaviviral infections occurring across the Eurasian land mass. In the Far East, the disease is called Russian spring-summer encephalitis; the milder, often biphasic form in Europe is simply called tick-borne encephalitis. TBE is found in all countries of Europe except Portugal and the Benelux countries. The incidence is particularly high in Austria, Poland, Hungary, Czech Republic, Slovakia, former Yugoslavia, and Russia. The incidence tends to be very focal. Seroprevalence is as high as 50% in farm and forestry workers. The majority of cases occur in adults, but even young children may be infected while playing in the woods or on picnics or camping trips. The seasonal distribution of cases is midsummer in southern Europe, with a longer season in Scandinavia and the Russian Far East. TBE can be excreted from the milk of goats, sheep, or cows. Before World War II, when milk was consumed unpasteurized, milk-borne cases were common.

Viruses are transmitted principally by hard ticks of *Ixodes ricinus* in Europe and *Ixodes persulcatus* in the Far East. Viral circulation is maintained by a combination of transmission from ticks to birds, rodents, and larger mammals and transtadial transmission from larval to nymphal and adult stages. In some parts of Europe and Russia, ticks feed actively during the spring and early fall, giving rise to the name spring-summer encephalitis.

Clinical Manifestations.

After an incubation period of 7–14 days, the European form begins as an acute nonspecific febrile illness followed in 5–30% of cases by meningoencephalitis. The Far Eastern variety more often results in encephalitis with higher case fatality and sequelae rates. The first phase of illness is characterized by fever, headache, myalgia, malaise, nausea, and vomiting for 2–7 days. Fever disappears and after 2–8 days may return accompanied by vomiting, photophobia, and signs of meningeal irritation in children and more severe encephalitic signs in adults. This phase rarely lasts more than 1 wk.

Diagnosis.

The diagnosis of TBE should be suspected in patients reporting a tick bite in endemic areas during the transmission season. The etiologic diagnosis of TBE is established by testing an acute-phase serum collected early in the illness for the presence of virus-specific IgM antibodies or, alternatively, demonstrating a fourfold or greater increase in IgG antibody titers by testing paired acute and convalescent sera. The virus can also be identified by PCR.

Treatment.

There is no specific treatment for TBE. The treatment is intensive supportive care (Chapter 57), including control of seizures (Chapter 586).

Prognosis.

The main risk for fatal outcome is advanced age; the fatality rate in adults is about 1%, but sequelae in children are rare. Transient unilateral paralysis of an upper extremity is a common finding in adults. Common sequelae include chronic fatigue, headache, sleep disorders, and emotional disturbances.

Prevention.

Specific Ig has been given to persons with seasonal tick bite exposure, although efficacy of this preventive therapy is not well studied. Effective inactivated vaccines for human use, made from virus grown in tissue culture, are licensed in Russia and

Europe. They are administered in a three-dose series, as described for JE vaccine.

Chapter 246 - Dengue Fever and Dengue Hemorrhagic Fever

Scott B. Halstead

Dengue fever, a benign syndrome caused by several arthropod-borne viruses, is characterized by biphasic fever, myalgia or arthralgia, rash, leukopenia, and lymphadenopathy. **Dengue hemorrhagic fever** (Philippine, Thai, or Singapore hemorrhagic fever; hemorrhagic dengue; acute infectious thrombocytopenic purpura) is a severe, often fatal, febrile disease caused by dengue viruses. It is characterized by capillary permeability, abnormalities of hemostasis, and, in severe cases, a protein-losing shock syndrome (**dengue shock syndrome**). It is currently thought to have an immunopathologic basis.

Etiology.

There are at least four distinct antigenic types of dengue virus, members of the family Flaviviridae. In addition, three other *ar*thropod-*bo*rne (*arbo*viruses) cause similar or identical febrile diseases with rash (Table 246–1).

Epidemiology.

Dengue viruses are transmitted by mosquitoes of the *Stegomyia* family. *Aedes aegypti*, a daytime biting mosquito, is the principal vector, and all four virus types have been recovered from it. In most tropical areas, *A. aegypti* is highly urbanized, breeding in water stored for drinking or bathing and in rainwater collected in any container. Dengue viruses have also been recovered from *Aedes albopictus*, as in the 2001 Hawaiian epidemic, while outbreaks in the Pacific area have been attributed to several other *Aedes* species. These species breed in water trapped in vegetation. In Southeast Asia and West Africa, dengue may be maintained in a cycle involving canopy-feeding jungle monkeys and *Aedes* species, which feed on monkeys.

Epidemics were common in temperate areas of the Americas, Europe, Australia, and Asia until early in the 20th century. Dengue fever and dengue-like disease are now

endemic in tropical Asia, the South Pacific Islands, northern Australia, tropical Africa, the Caribbean, and Central and South America. Dengue fever occurs frequently among travelers to these areas.

Dengue outbreaks in urban areas infested with *A. aegypti* may be explosive; up to 70–80% of the population may be involved. Most disease occurs in older children and adults. Because *A. aegypti* has a limited range, spread of an epidemic occurs mainly through viremic human beings and follows the main lines of transportation. Sentinel cases may infect household mosquitoes; a large number of nearly simultaneous secondary infections give the appearance of a contagious disease. Where dengue is endemic, children and susceptible foreigners may be the only persons to acquire overt disease, adults having become immune.

DENGUE-LIKE DISEASES.

Dengue-like diseases may also occur in epidemics. Epidemiologic features depend on the

TABLE 246-1 -- **Vectors and Geographic Distribution of Dengue-Like Diseases**

Genus	Virus and Disease	Vector	Geographic Distribution
Togavirus	Chikungunya	*Aedes aegypti Aedes africanus*	Africa, India, Southeast Asia
Togavirus	O'nyong-nyong	*Anopheles funestus*	East Africa
Flavivirus	West Nile fever	*Culex molestus Culex univittatus*	Europe, Africa, Middle East, India

vectors and their geographic distribution (see Table 246–1). Chikungunya virus is widespread in the most populous areas of the world. In Asia, *A. aegypti* is the principal vector; in Africa, other *Stegomyia* may be important vectors. In Southeast Asia, dengue and chikungunya outbreaks occur concurrently. Outbreaks of o'nyong-nyong and West Nile fever usually involve villages or small towns, in contrast to the urban outbreaks of dengue and chikungunya.

DENGUE HEMORRHAGIC FEVER.

Dengue hemorrhagic fever occurs where multiple types of dengue virus are simultaneously or sequentially transmitted. Currently, it is endemic in all of tropical America and Asia, where warm temperatures and the practices of water storage in homes plus outdoor breeding sites result in large, permanent populations of *A. aegypti.* Under these conditions, infections with dengue viruses of all types are common, and second infections with heterologous types are frequent.

Second dengue infections are relatively mild in the majority of instances, ranging from an inapparent infection through an undifferentiated upper respiratory tract or dengue-like disease, but may also progress to dengue hemorrhagic fever. Nonimmune foreigners, adults and children, exposed to dengue virus during outbreaks of hemorrhagic fever have classic dengue fever or even milder disease. The differences in clinical manifestations of dengue infections between natives and foreigners in Southeast Asia are related more to immunologic status than to racial susceptibility. Dengue hemorrhagic fever can occur during primary dengue infections, most frequently in infants whose mothers are immune to dengue.

Dengue 3 virus strains circulating in mainland Southeast Asia since 1983 are associated with a particularly severe clinical syndrome, characterized by encephalopathy, hypoglycemia, markedly elevated liver enzymes, and, occasionally, jaundice.

Pathogenesis.

The pathogenesis of dengue fever is not clear. Fatalities with chikungunya and West Nile fever infections have been ascribed to viral encephalitis or hemorrhage.

The pathogenesis is incompletely understood, but epidemiologic studies suggest that it is usually associated with second infections with dengue types 1–4. In the Americas, dengue hemorrhagic fever and dengue shock syndrome have been associated only with dengue 2 strains of recent Southeast Asian origin. Recent occurrences of sizable dengue hemorrhagic fever outbreaks in India, Pakistan, and Bangladesh also appear to be related to imported dengue strains. Dengue viruses demonstrate enhanced growth in cultures of human mononuclear phagocytes prepared from dengue-immune donors or in cultures supplemented with non-neutralizing dengue antibodies. Retrospective studies of sera from human mothers whose infants acquired dengue hemorrhagic fever or prospective studies in children acquiring sequential dengue infections have shown that the circulation of infection-enhancing antibodies at the time of infection is the strongest risk factor for development of severe disease. Monkeys infected sequentially or receiving small quantities of enhancing antibodies have enhanced viremias. In humans studied early during the course of secondary dengue infections, viremia levels directly predicted disease severity. Early in the acute stage of secondary dengue infections, there is rapid activation of the complement system. Shortly before or during shock, blood levels of soluble tumor necrosis factor receptor, interferon-?, and interleukin 2 are elevated. C1q, C3, C4, C5–C8, and C3 proactivators are depressed, and C3 catabolic rates are elevated. These factors may interact at the endothelial cell to produce increased vascular permeability through the nitric oxide final pathway. The blood clotting and fibrinolytic systems are activated, and levels of factor XII (Hageman factor) are depressed. The mechanism of bleeding in dengue hemorrhagic fever is not known, but a mild degree of disseminated intravascular coagulation, liver damage, and thrombocytopenia

may operate synergistically. Capillary damage allows fluid, electrolytes, small

proteins, and, in some instances, red cells to leak into extravascular spaces. This internal redistribution of fluid, together with deficits caused by fasting, thirsting, and vomiting, results in hemoconcentration, hypovolemia, increased cardiac work, tissue hypoxia, metabolic acidosis, and hyponatremia.

Usually no pathologic lesions are found to account for death. In rare instances, death may be due to gastrointestinal or intracranial hemorrhages. Minimal to moderate hemorrhages are seen in the upper gastrointestinal tract, and petechial hemorrhages are common in the interventricular septum of the heart, on the pericardium, and on the subserosal surfaces of major viscera. Focal hemorrhages are occasionally seen in the lungs, liver, adrenals, and subarachnoid space. The liver is usually enlarged, often with fatty changes. Yellow, watery, and at times blood-tinged effusions are present in serous cavities in about three fourths of patients.

Microscopically, there is perivascular edema in the soft tissues and widespread diapedesis of red cells. There may be maturational arrest of megakaryocytes in bone marrow, and increased numbers of them are seen in capillaries of the lungs, in renal glomeruli, and in sinusoids of the liver and spleen.

Dengue virus is usually absent in tissues at the time of death; rare isolations have been reported from liver and lymphatic tissues, most often in children <1 yr of age with primary infection.

Clinical Manifestations.

The incubation period is 1–7 days. The clinical manifestations are variable and are influenced by the age of the patient. In infants and young children, the disease may be undifferentiated or characterized by fever for 1–5 days, pharyngeal inflammation, rhinitis, and mild cough. A majority of infected older children and adults experience sudden onset of fever, with temperature rapidly increasing to 39.4–41.1°C (103–106°F), usually accompanied by frontal or retro-orbital pain, particularly when pressure is applied to the eyes. Occasionally, severe back pain precedes the fever (back-break fever). A *transient*, macular, generalized rash that blanches under pressure may be seen during the first 24–48?hr of fever. The pulse rate may be slow relative to the degree of fever. Myalgia and arthralgia occur soon after the onset and increase in severity. Joint symptoms may be particularly severe in patients with chikungunya or o'nyong-nyong infection. From the 2nd–6th days of fever, nausea and vomiting are apt to occur, and generalized lymphadenopathy, cutaneous hyperesthesia or hyperalgesia, taste aberrations, and pronounced anorexia may develop.

About 1–2 days after defervescence, a generalized, morbilliform, maculopapular rash appears that spares the palms and soles. It disappears in 1–5 days; desquamation may occur. Rarely there is edema of the palms and soles. About the time this second rash appears, the body temperature, which has previously decreased to normal, may become slightly elevated and demonstrate the characteristic biphasic temperature pattern.

DENGUE HEMORRHAGIC FEVER.

Differentiation between dengue fever and dengue hemorrhagic fever is difficult early in the course of illness. A relatively mild first phase with abrupt onset of fever, malaise, vomiting, headache, anorexia, and cough is followed after 2–5 days by rapid clinical deterioration and collapse. In this second phase, the patient usually has cold, clammy extremities, a warm trunk, flushed face, diaphoresis, restlessness, irritability, and midepigastric pain. Frequently, there are scattered petechiae on the forehead and extremities; spontaneous ecchymoses may appear, and easy bruising and bleeding at sites of venipuncture are common. A macular or maculopapular rash may appear, and there may be circumoral and peripheral cyanosis. Respirations are rapid and often labored. The pulse is weak, rapid, and thready and the heart sounds faint. The liver may enlarge to 4–6?cm below the costal margin and is usually firm and somewhat tender. Approximately 20–30% of cases of dengue hemorrhagic fever are complicated by shock (dengue shock syndrome). Fewer than 10% of patients have gross ecchymosis or gastrointestinal bleeding, usually after a period of uncorrected shock. After a 24–36?hr period of crisis, convalescence is fairly rapid in the children who recover. The temperature may return to normal before or during the stage of shock. Bradycardia and ventricular extrasystoles are common during convalescence.

Diagnosis.

A clinical diagnosis of dengue fever derives from a high index of suspicion and a knowledge of the geographic distribution and environmental cycles of causal viruses. Because clinical findings vary and there are many possible causative agents, the term “dengue-like disease” should be used until a specific diagnosis is established.

The World Health Organization criteria for **dengue hemorrhagic fever** are fever, minor or major hemorrhagic manifestations, thrombocytopenia (=100,000/mm^3), and objective evidence of increased capillary permeability (hematocrit increased =20%), pleural effusion (by chest radiograph), or hypoalbuminemia. **Dengue shock syndrome** criteria include those for dengue hemorrhagic fever as well as hypotension or narrow pulse pressure (=20?mm Hg).

Virologic diagnosis can be established by serologic tests or by isolation of the virus from blood leukocytes or serum. In both primary and secondary dengue infections, there is a relatively transient appearance of antidengue immunoglobulin (Ig) M antibodies. These disappear after 6–12 wk, which can be used to time a dengue infection. In second primary dengue infections, most antibody is of the IgG class. Serologic diagnosis depends on a fourfold or greater increase in IgG antibody titer in paired sera by hemagglutination inhibition, complement fixation, enzyme immunoassay, or neutralization test. Carefully standardized immunoglobulin IgM- and IgG-capture enzyme immunoassays are now widely used to identify acute-phase antibodies from patients with primary or secondary dengue infections in single-serum samples. Usually such samples should be collected not earlier than 5 days nor later than 6 wk after onset. It may not be possible to distinguish the infecting virus by serologic methods alone, particularly when there has been prior infection with another member of the same arbovirus group. Virus can be recovered from acute-phase serum after inoculating tissue culture or living mosquitoes. Viral RNA can be detected in blood or tissues by specific complementary DNA probes or amplified first by the polymerase chain reaction.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis of dengue fever includes viral respiratory and influenza-like diseases, the early stages of malaria, mild yellow fever, scrub typhus, viral hepatitis, and leptospirosis.

Four arboviral diseases have dengue-like courses but without rash: Colorado tick fever, sandfly fever, Rift Valley fever, and Ross River fever. Colorado tick fever occurs sporadically among campers and hunters in the western United States; sandfly fever in the Mediterranean region, the Middle East, southern Russia, and parts of the Indian subcontinent; and Rift Valley fever in North, East, Central, and South Africa. Ross River fever is endemic in much of eastern Australia with epidemic extension to Fiji. In adults, Ross River fever often produces protracted and crippling arthralgia involving weight-bearing joints.

Because meningococcemia, yellow fever (Chapter 247), other viral hemorrhagic fevers (Chapter 248), many rickettsial diseases, and other severe illnesses caused by a variety of agents may produce a clinical picture similar to dengue hemorrhagic fever, the etiologic diagnosis should be made only when epidemiologic or serologic evidence suggests the possibility of a dengue infection.

LABORATORY FINDINGS.

In dengue fever, pancytopenia may occur after the 3–4 days of illness. Neutropenia may persist or reappear during the latter stage of the disease and

---

may continue into convalescence with white blood cell counts as low as 2,000/mm^3 . Platelets rarely fall below 100,000/mm^3 . Venous clotting, bleeding and prothrombin times, and plasma fibrinogen values are within normal ranges. The tourniquet test infrequently is positive. Mild acidosis, hemoconcentration, increased transaminase values, and hypoproteinemia may occur during some primary dengue virus infections. The electrocardiogram may show sinus bradycardia, ectopic ventricular foci, flattened T waves, and prolongation of the P-R interval.

The most common hematologic abnormalities during dengue hemorrhagic fever and dengue shock syndrome are hemoconcentration with an increase of >20% in hematocrit, thrombocytopenia, prolonged bleeding time, and moderately decreased prothrombin level that is seldom <40% of control. Fibrinogen levels may be subnormal and fibrin split products elevated. Other abnormalities include moderate elevations of the serum transaminase levels, consumption of complement, mild metabolic acidosis with hyponatremia, and occasionally hypochloremia, slight elevation of serum urea nitrogen, and hypoalbuminemia. Roentgenograms of the chest reveal pleural effusions (left > right) in nearly all patients.

Treatment.

Treatment of uncomplicated dengue fever is supportive. Bed rest is advised during the febrile period. Antipyretics should be used to keep body temperature less than 40℃ (104℉). Analgesics or mild sedation may be required to control pain. Aspirin is contraindicated and should not be used because of its effects on hemostasis. Fluid and electrolyte replacement is required for deficits caused by sweating, fasting, thirsting, vomiting, and diarrhea.

DENGUE HEMORRHAGIC FEVER.

Management of dengue hemorrhagic fever and dengue shock syndrome includes immediate evaluation of vital signs and degrees of hemoconcentration, dehydration, and electrolyte imbalance. Close monitoring is essential for at least 48?hr because shock may occur or recur precipitously early in the disease. Patients who are cyanotic or have labored breathing should be given oxygen. Rapid intravenous replacement of fluids and electrolytes can frequently sustain patients until spontaneous recovery occurs. Normal saline is more effective in treating shock than the more expensive Ringer lactated saline. When pulse pressure is =10?mmHg, or when elevation of the hematocrit persists after replacement of fluids, plasma or colloid preparations are indicated.

Care must be taken to avoid overhydration, which may contribute to cardiac failure. Transfusions of fresh blood or platelets suspended in plasma may be required to control bleeding; they should not be given during hemoconcentration but only after evaluation of hemoglobin or hematocrit values. Salicylates are contraindicated because of their effect on blood clotting.

Paraldehyde or chloral hydrate may be required for children who are markedly agitated. Use of vasopressors has not resulted in a significant reduction of mortality compared with that observed with simple supportive therapy. Disseminated intravascular coagulation may require treatment (Chapter 475). Corticosteroids do not shorten the duration of disease or improve prognosis in children receiving careful supportive therapy.

Hypervolemia during the fluid reabsorptive phase may be life-threatening and is heralded by a decrease in hematocrit with wide pulse pressure. Diuretics and digitalization may be necessary.

Complications.

Primary infections with dengue fever and dengue-like diseases are usually self-limited and benign. Fluid and electrolyte losses, hyperpyrexia, and febrile convulsions are the most frequent complications in infants and young children. Epistaxis, petechiae, and purpuric lesions are uncommon but may occur at any stage. Swallowed blood from epistaxis, vomited or passed by rectum, may be erroneously interpreted as gastrointestinal bleeding. In adults and possibly in children, underlying conditions may lead to clinically significant bleeding. Convulsions may occur during high temperature especially with chikungunya fever. Infrequently, after the febrile stage, prolonged asthenia, mental depression,

bradycardia, and ventricular extrasystoles may occur in children.

In endemic areas, dengue hemorrhagic fever should be suspected in children with a febrile illness suggestive of dengue fever who experience hemoconcentration and thrombocytopenia.

Prognosis.

The prognosis of dengue fever may be adversely affected by passively acquired antibody or by prior infection with a closely related virus that predisposes to development of dengue hemorrhagic fever.

DENGUE HEMORRHAGIC FEVER.

Death has occurred in 40–50% of patients with shock, but with adequate intensive care deaths should occur in less than 1% of cases. Survival is directly related to early and intense supportive treatment. Infrequently, there is residual brain damage caused by prolonged shock or occasionally by intracranial hemorrhage.

Prevention.

Several types of dengue types 1, 2, 3, and 4 vaccines are under development, and a killed vaccine for chikungunya is efficacious but not generally available. Prophylaxis consists of avoiding mosquito bites by use of insecticides, repellents, body covering with clothing, screening of houses, and destruction of *A. aegypti* breeding sites (Chapter 285). If water storage is mandatory, a tight-fitting lid or a thin layer of oil may prevent egg laying or hatching. A larvicide, such as Abate [O,O'-(thiodi-*p*-phenylene) O,O,O,O'-tetramethyl phosphorothioate], available as a 1% sand-granule formation and effective at a concentration of 1?ppm, may be added safely to drinking water. Ultra-low-volume spray equipment effectively dispenses the adulticide malathion from truck or airplane for rapid intervention during an epidemic. Only personal antimosquito measures are effective against mosquitoes in the field, forest, or jungle.

The possibility exists that dengue vaccination may sensitize a recipient so that ensuing dengue infection could result in hemorrhagic fever. Vaccination with yellow fever 17D strain has no effect on the severity of dengue illness, although seroconversion rates to a dengue 2 vaccine were enhanced in persons immune to yellow fever.

Chapter 247 - Yellow Fever

Scott B. Halstead

Yellow fever is an acute infection characterized in its most severe form by fever, jaundice, proteinuria, and hemorrhage. The virus is mosquito-borne and occurs in epidemic or endemic form in South America and Africa. Seasonal epidemics occurred in cities located in temperate areas of Europe and the Americas until 1900; epidemics continue to occur in West, Central, and East Africa.

Etiology.

Yellow fever is the prototype of the *Flavivirus* genus of the family Flaviviridae, which are enveloped single-stranded RNA viruses 35–50?nm in diameter.

Yellow fever circulates zoonotically as three genotypes: type I and IIA in Central and West Africa, respectively, and type IIB in South America. The type IIA virus is capable of urban transmission between human beings by *Aedes aegypti*. Sometime in the 1600s, this virus was brought to the American tropics through the African slave trade. Subsequently, yellow fever caused enormous coastal and riverine epidemics until the 20th century, when the virus and its urban and sylvan mosquito cycles were identified and a vaccine and mosquito control developed.

Epidemiology.

Human and nonhuman primate hosts acquire the infection by the bite of infected mosquitoes. After an incubation period of 3–6 days, virus appears in the blood and may serve as a source of infection for other mosquitoes. The virus must replicate in the gut of the mosquito and pass to the salivary gland before the mosquito can transmit the virus. Yellow fever virus is transmitted in an urban cycle—human to *A. aegypti* to human—and a jungle cycle—monkey to jungle mosquitoes to monkey. Classic yellow fever epidemics in the United States, South America, the Caribbean, and parts of Europe were of the urban variety. Present-day African epidemics are primarily urban. Most of the approximately 200 cases reported each year in South America are jungle yellow fever. In colonial times, attack rates in white adults were very high, suggesting that subclinical infections are uncommon in this age group.

Yellow fever may be less severe in children, with subclinical infections to clinical case ratios of =2:1. In areas where outbreaks of urban yellow fever are common, most cases involve children because many adults are immune. Transmission in West Africa is highest during the rainy season, from July to November. The migration of nonimmune laborers into endemic regions is a significant factor in some outbreaks.

In tropical forests, yellow fever virus is maintained in a transmission cycle involving monkeys and tree hole–breeding mosquitoes (*Haemagogus* in Central and South America, *Aedes africanus* in Africa). In the Americas, most cases involve men who work in forested areas and are exposed to infected mosquitoes. In Africa, the virus is prevalent in moist savanna and savanna transition areas where other tree hole–breeding *Aedes* vectors transmit the virus between monkeys and humans and between humans.

Pathogenesis.

Pathologic changes seen in the liver include (1) coagulative necrosis of hepatocytes in the midzone of the liver lobule, with sparing of cells around the portal areas and central veins; (2) eosinophilic degeneration of hepatocytes (**Councilman bodies**); (3) microvacuolar fatty change; and (4) minimal inflammation. The kidneys show acute tubular necrosis. In the heart, myocardial fiber degeneration and fatty infiltration are seen. The brain may show edema and petechial hemorrhages. Direct viral injury to the liver results in impaired ability to perform functions of biosynthesis and detoxification; this is the central pathogenic event of yellow fever. Hemorrhage is thought to result from decreased synthesis of vitamin K–dependent clotting factors and, in some cases, disseminated intravascular clotting. Renal dysfunction has been attributed to hemodynamic factors (prerenal failure progressing to acute tubular necrosis). The pathogenesis of shock in patients with yellow fever appears to be similar to that described in dengue shock syndrome and the other viral hemorrhagic fevers.

Clinical Manifestations.

In Africa, inapparent, abortive, or clinically mild infections are frequent; some studies suggest that children experience a milder disease than adults do. Abortive infections, characterized by fever and headache, may be unrecognized except during epidemics.

In its classic form, yellow fever begins with sudden onset of fever, headache, myalgia, lumbosacral pain, anorexia, nausea, and vomiting. Physical findings during the early phase of illness, when virus is present in the blood, include prostration, conjunctival injection, flushing of face and neck, reddening of the tongue at the tip and edges, and relative bradycardia. After 2–3 days, there may be a brief period of remission, followed in 6–24?hr by reappearance of fever with vomiting, epigastric pain, jaundice, dehydration, gastrointestinal and other hemorrhages, albuminuria, hypotension, signs of renal failure, delirium, convulsions, and coma. Death may occur between the 7th and 10th days. The fatality rate in severe cases approaches 50%. Some patients who survive the acute phase of illness later succumb to renal failure or myocardial damage. Laboratory abnormalities include leukopenia; prolonged clotting, prothrombin, and partial thromboplastin times; thrombocytopenia; hyperbilirubinemia; elevated serum transaminases; albuminuria; and azotemia.

Hypoglycemia may be present in severe cases. Electrocardiogram abnormalities characterized by bradycardia and ST-T changes are described.

Diagnosis.

Yellow fever should be suspected when fever, headache, vomiting, myalgia, and jaundice appear in residents of endemic areas or in unimmunized visitors who have recently traveled (within 2 wk before onset of symptoms) to endemic areas. Clinically, yellow fever is quite similar to dengue hemorrhagic fever. In contrast to the gradual onset of acute viral hepatitis resulting from types hepatitis A, B, C, D, or E viruses, jaundice in yellow fever appears after 3–5 days of high temperature and is often accompanied by severe prostration. Mild yellow fever is dengue-like and cannot be distinguished from a wide variety of other infections. Jaundice and fever may occur in any of several other tropical diseases, including malaria, viral hepatitis, louse-borne relapsing fever, leptospirosis, typhoid fever, rickettsial infections, certain systemic bacterial infections, sickle cell crisis, Rift Valley fever, Crimean-Congo hemorrhagic fever, and other viral hemorrhagic fevers. Outbreaks of yellow fever always include cases with severe gastrointestinal hemorrhage.

Specific diagnosis depends on detection of virus or viral antigen in acute-phase blood samples or antibody assays. The immunoglobulin M enzyme immunoassay is particularly useful. Sera obtained during the first 10 days after onset of symptoms should be kept in an ultra-low-temperature freezer (-70°C) and shipped on dry ice for virus testing. Convalescent-phase samples for antibody tests are managed by conventional means. In handling acute-phase blood specimens, medical personnel must take care to avoid contaminating themselves or others on the evacuation trail (laboratory personnel and others). Postmortem diagnosis is based on virus isolation from liver or blood, identification of Councilman bodies in liver tissue, or detection of antigen or viral genome in liver tissue.

Treatment.

It is customary to keep yellow fever patients in a mosquito-free area, using mosquito nets if necessary. Patients are viremic during the febrile phase of the illness. Although there is no specific treatment for yellow fever, medical care is directed at maintaining physiologic status: (1) sponging and acetaminophen to reduce high temperature, (2) vigorous fluid replacement of losses resulting from fasting, thirsting, vomiting, or plasma leakage, (3) correcting acid-base imbalance, (4) maintaining nutritional intake to lessen the severity of hypoglycemia, and (5) avoiding drugs that are either metabolized by the liver or toxic to the liver, kidney, or central nervous system.

Complications.

Complications of acute yellow fever include severe hemorrhage, liver failure, and acute renal failure. Bleeding should be managed by transfusion of fresh whole blood or fresh plasma with platelet concentrates if necessary. Renal failure may require peritoneal dialysis or hemodialysis.

Prevention.

Yellow fever 17D is a live, attenuated vaccine with a long record of safety and efficacy. It is administered as a single 0.5-mL subcutaneous injection at least 10 days before arrival in a yellow fever endemic area. All persons traveling to endemic areas in South America and Africa should be considered for vaccination, but length of stay, exact locations to be visited, and environmental or occupational exposure may determine the specific risk and individual need for vaccination. Persons traveling from yellow fever–endemic to yellow fever–receptive countries may be required to obtain a yellow fever vaccine (e.g., from South America or Africa to India). Usually countries that require travelers to obtain a yellow fever immunization do not issue a visa without a valid immunization certificate. Vaccination is valid for 10 yr for international travel certification, although immunity lasts at least 40 yr and probably for life.

Yellow fever vaccine should not be administered to persons with symptomatic immunodeficiency diseases and those taking immunosuppressant drugs. Although the vaccine is not known to harm fetuses, its administration during pregnancy is not advised. In very young children, there is a small risk of encephalitis and death after yellow fever 17D vaccination. The 17D vaccine should not be administered to infants younger than 4 mo because nearly all neurologic complications occur in this age group. Questions have been raised about the safety of 17D vaccine in older individuals. Several cases of fatal yellow fever-like disease have been reported in elderly recipients of 17D vaccine. Residence or travel to areas of known or anticipated yellow fever activity (e.g., forested areas in the Amazon basin), which places an individual at high risk, warrants immunization of infants 4–9 mo of age. Immunization of children =9 mo of age is routinely recommended before entry into endemic areas. Vaccination should be avoided for persons with a history of egg allergy. Alternatively, a skin test can be performed to determine whether a serious allergy exists that would preclude vaccination.

Chapter 248 - Other Viral Hemorrhagic Fevers

Scott B. Halstead

Viral hemorrhagic fevers are a loosely defined group of clinical syndromes in which hemorrhagic manifestations are either common or especially notable in severe illness. Both the etiologic agents and clinical features of the syndromes differ, but disseminated intravascular coagulopathy may be a common pathogenetic feature.

Etiology.

Six of the viral hemorrhagic fevers are caused by *ar*thropod-*bo*rne (arboviruses) viruses (Table 248–1). Four are togaviruses of the family Flaviviridae, including Kyasanur Forest disease, Omsk, dengue (Chapter 246), and yellow fever (Chapter 247) viruses. Three are of the family Bunyaviridae, including Congo, Hantaan, and Rift Valley fever viruses. Four are of the family Arenaviridae, including Junin, Machupo, Guanarito, and Lassa viruses. Two are of the family Filoviridae, including Ebola and Marburg viruses. The Filoviridae are enveloped, filamentous RNA viruses, which are sometimes branched, unlike any other known virus.

Epidemiology and Clinical Manifestations.

With some exceptions, the viruses causing viral hemorrhagic fevers are transmitted to humans via a nonhuman entity. The specific ecosystem required for viral survival determines the geographic distribution of disease. Although it is commonly thought that all viral hemorrhagic fevers are arthropod-borne, seven may be contracted from environmental contamination caused by animals or animal cells or from infected humans (see Table 248–1). Laboratory and hospital infections have occurred with many of these agents. Lassa fever and Argentine and Bolivian hemorrhagic fevers are reportedly milder in children than in adults.

CRIMEAN-CONGO HEMORRHAGIC FEVER.

Sporadic human infection in Africa provided the original virus isolation. Natural foci are recognized in Bulgaria, western Crimea, and the Rostov-on-Don and Astrakhan regions; a somewhat similar disease occurs in Kazakhstan and Uzbekistan. Index cases were followed by nosocomial transmission in Pakistan and Afghanistan

TABLE 248-1 -- Viral Hemorrhage Fevers

Mode of Transmission	Disease	Virus
Tick borne	Crimean-Congo HF*	Congo
	Kyasanur Forest disease	Kyasanur Forest disease
	Omsk HF	Omsk
Mosquito borne†	Dengue HF	Dengue (four types)
	Rift Valley fever	Rift Valley fever
	Yellow fever	Yellow fever
Infected animals or materials to humans	Argentine HF	Junin
	Bolivian HF	Machupo
	Lassa fever*	Lassa
	Marburg disease*	Marburg
	Ebola HF*	Ebola
	Hemorrhagic fever with renal syndrome	Hantaan

HF = hemorrhagic fever.

**Patients may be contagious; nosocomial infections are common.*

† Chikungunya virus is associated at low frequency with petechiae, petechial hemorrhages, and epistaxis. More severe hemorrhagic manifestations have been reported in some studies.

in 1976, in the Arabian Peninsula in 1983, and in South Africa in 1984. Recent outbreaks have been reported from Pakistan, Oman, and southern Russia. In the Russian Federation, the vectors are *Hyalomma marginatum* and *Hyalomma anatolicum,* which, along with hares and birds, may serve as viral reservoirs. Disease occurs from June to September, largely among farmers and dairy workers.

KYASANUR FOREST DISEASE.

Human cases occur chiefly in adults in an area of Mysore State, India. The main vectors are two *Ixodidae* ticks, *Haemaphysalis turturis* and *Haemaphysalis spinigera.* Monkeys and forest rodents may be amplifying hosts. Laboratory infections are common.

OMSK HEMORRHAGIC FEVER.

The disease occurs throughout south central Russia and northern Romania. Vectors may include *Dermacentor pictus* and *Dermacentor marginatus,* but direct transmission from moles and muskrats to humans seems well established. Human disease occurs in a spring-summer-autumn pattern, paralleling the activity of vectors. This infection occurs most frequently in persons with outdoor occupational exposure. Laboratory infections are common.

RIFT VALLEY FEVER.

The virus causing Rift Valley fever is responsible for epizootics involving sheep, cattle, buffalo, certain antelopes, and rodents in North, Central, East, and South Africa. The virus is transmitted to domestic animals by *Culex theileri* and several *Aedes* species. Mosquitoes may serve as reservoirs by transovarial transmission. An epizootic in Egypt in 1977–78 was accompanied by thousands of human infections, principally among veterinarians, farmers, and farm laborers. Smaller outbreaks occurred in Senegal in 1987, Madagascar in 1990, and Saudi Arabia and Yemen in 2000–2001. Humans are most often infected during the slaughter or skinning of sick or dead animals. Laboratory infection is common.

ARGENTINE HEMORRHAGIC FEVER.

Before introduction of vaccine, hundreds to thousands of cases occurred annually from April through July in the maize-producing area northwest of Buenos Aires that reaches to the eastern margin of the Province of Cordoba. Junin virus has been isolated from the rodents *Mus musculus, Akodon arenicola,* and *Calomys laucha laucha.* It infects migrant laborers who harvest the maize and who inhabit rodent-contaminated shelters.

BOLIVIAN HEMORRHAGIC FEVER.

The recognized endemic area consists of the sparsely populated province of Beni in Amazonian Bolivia. Sporadic cases occur in farm families who raise maize, rice, yucca, and beans. In the town of San Joaquin, a disturbance in the domestic rodent ecosystem may have led to an outbreak of household infection caused by *Calomys callosus,* ordinarily a field rodent. Mortality rates are high in young children.

VENEZUELAN HEMORRHAGIC FEVER.

In 1989, an outbreak of hemorrhagic illness occurred in the farming community of Guanarito, Venezuela, 200 miles south of Caracas. Subsequently, in 1990–1991, there were 104 cases reported with 26 deaths. Cotton rats (*Sigmodon alstoni*) and cane rats (*Zygodontomys brevicauda*) have been implicated as likely reservoirs.

LASSA FEVER.

Lassa virus has an unusual potential for human-to-human spread and has resulted in many small epidemics in Nigeria, Sierra Leone, and Liberia. Medical workers in Africa and the United States have also contracted the disease. Patients with acute Lassa fever have been transported by international aircraft, necessitating extensive surveillance among passengers and crews. The virus is probably maintained in nature in a species of African peridomestic rodent, *Mastomys natalensis.*

Rodent-to-rodent transmission and infection of humans probably operate via mechanisms established for other arenaviruses.

MARBURG DISEASE.

Until recently, the world experience has been limited to 26 primary and five secondary cases in Germany and Yugoslavia in 1967, to small outbreaks in Zimbabwe in 1975, Kenya in 1980 and 1988, South Africa in 1983, and a large outbreak in Congo Republic in 1999. Transmission occurs by direct contact with tissues of the African green monkey, with infected blood, or with human semen. The reservoir and mode of transmission of the virus in nature are unknown.

EBOLA HEMORRHAGIC FEVER.

Ebola virus was isolated in 1976 from a devastating epidemic involving small villages in northern Zaire and southern Sudan; smaller outbreaks have occurred subsequently. Outbreaks initially have been nosocomial. Attack rates have been highest in the birth–1 yr and 15–50 yr old age groups. The virus resembles Marburg virus. Ebola virus has been particularly active recently, with a well-known outbreak in Kikwit, Zaire, in 1995, followed recently by scattered outbreaks in Uganda and Central and West Africa. The virus has been recovered from chimpanzees, but the vertebrate reservoir and mode of transmission to humans are unknown. Reston virus, related to Ebola, has been recovered from Philippine monkeys and has caused subclinical infections in workers in monkey colonies in the United States.

HEMORRHAGIC FEVER WITH RENAL SYNDROME (HFRS).

The endemic area of HFRS, also known as **epidemic hemorrhagic fever** and **Korean hemorrhagic fever**, includes Japan, Korea, Far Eastern Siberia, north and central China, European and Asian Russia, Scandinavia, Czechoslovakia, Romania, Bulgaria, Yugoslavia, and Greece. Although the incidence and severity of hemorrhagic manifestations and the mortality are lower in Europe than in northeastern Asia, the renal lesion is the same. Disease in Scandinavia, **nephropathia epidemica,** is caused by a different although antigenically related virus, Puumala virus, associated with the bank vole, *Clethrionomys glareolus.* Cases occur predominantly in the spring and summer. There appears to be no age factor in susceptibility, but because of occupational hazards, young adult men are most frequently attacked. Rodent plagues and evidence of rodent infestation have accompanied endemic and epidemic occurrences. Hantaan virus has been detected in lung tissue and excreta of *Apodemus agrarius coreae.* Antigenically related agents have been detected in laboratory rats and in urban rat populations around the world, including Prospect Hill virus in the wild rodent *Microtus pennsylvanicus* in North America and Sin Nombre virus in the deer mouse in southern and southwestern United States; these viruses are causes of hantavirus pulmonary syndrome (Chapter 250). Rodent-to-rodent and rodent-to-human transmission presumably occurs via the respiratory route.

Clinical Manifestations.

Dengue hemorrhagic fever (Chapter 246) and yellow fever (Chapter 247) are more frequent causes of similar diseases in children in endemic areas.

CRIMEAN-CONGO HEMORRHAGIC FEVER.

The incubation period of 3–12 days is followed by a febrile period of 5–12 days and a prolonged convalescence. Illness begins suddenly with fever, severe headache, myalgia, abdominal pain, anorexia, nausea, and vomiting. After 1–2 days, fever may subside until the patient experiences an erythematous facial or truncal flush and injected conjunctivae. A second febrile period of 2–6 days then develops, with a hemorrhagic enanthem on the soft palate and a fine petechial rash on the chest and abdomen. Less frequently, there are large areas of purpura and bleeding from gums, nose, intestine, lungs, or uterus. Hematuria and proteinuria are relatively rare. During the hemorrhagic stage, there is usually tachycardia with diminished heart sounds and occasionally hypotension. The liver is usually enlarged, but there is no icterus. In protracted cases, central nervous system signs may include delirium, somnolence, and progressive clouding of consciousness. Early in the disease, leukopenia with relative lymphocytosis, progressively worsening thrombocytopenia, and gradually increasing anemia occur. In convalescence there may be hearing and memory loss. The mortality rate is 2–50%.

KYASANUR FOREST DISEASE AND OMSK HEMORRHAGIC FEVER.

After an incubation period of 3–8 days, both

diseases begin with sudden onset of fever and headache. Kyasanur Forest disease is characterized by severe myalgia, prostration, and bronchiolar involvement; it often presents without hemorrhage but occasionally with severe gastrointestinal bleeding. In Omsk hemorrhagic fever, there is moderate epistaxis, hematemesis, and a hemorrhagic enanthem but no profuse hemorrhage; bronchopneumonia is common. In both diseases, severe leukopenia and thrombocytopenia, vascular dilatation, increased vascular permeability, gastrointestinal hemorrhages, and subserosal and interstitial petechial hemorrhages occur. Kyasanur Forest disease may be complicated by acute degeneration of renal tubules and focal liver damage. In many patients, recurrent febrile illness may follow an afebrile period of 7–15 days. This second phase takes the form of a meningoencephalitis.

RIFT VALLEY FEVER.

Most infections have occurred in adults with disease similar to dengue fever (Chapter 246). Onset is acute, with fever, headache, prostration, myalgia, anorexia, nausea, vomiting, conjunctivitis, and lymphadenopathy. The fever lasts 3–6 days and is often biphasic. Convalescence is often prolonged. In the 1977–1978 outbreak, many patients died after showing signs that included purpura, epistaxis, hematemesis, and melena. At autopsy, there was extensive eosinophilic degeneration of the parenchymal cells of the liver.

ARGENTINE, VENEZUELAN, AND BOLIVIAN HEMORRHAGIC FEVER AND LASSA FEVER.

The incubation period is commonly 7–14 days; the acute illness lasts for 2–4 wk. Clinical illnesses range from undifferentiated fever to the characteristic severe illness. Lassa fever is most often clinically severe in whites. Onset is usually gradual, with increasing fever, headache, diffuse myalgia, and anorexia. During the 1st wk, signs frequently include a sore throat, dysphagia, cough, oropharyngeal ulcers, nausea, vomiting, diarrhea, and pains in chest and abdomen. Pleuritic chest pain may persist for 2–3 wk. In Argentine and Bolivian hemorrhagic fevers, and less frequently in Lassa fever, a petechial enanthem appears on the soft palate 3–5 days after onset and at about the same time on the trunk. The tourniquet test may be positive. The clinical course of Venezuelan hemorrhagic fever has not been well described.

In 35–50% of all patients, these diseases may become severe, with persistent high temperature, increasing toxicity, swelling of face or neck, microscopic hematuria, and frank hemorrhages from the stomach, intestines, nose, gums, and uterus. A syndrome of hypovolemic shock is accompanied by pleural effusion and renal failure. Respiratory distress resulting from airway obstruction, pleural effusion, or congestive heart failure may occur. A total of 10–20% of patients experience late neurologic involvement characterized by intention tremor of the tongue and associated speech abnormalities. In severe cases, there may be intention tremors of the extremities, seizures, and delirium. The cerebrospinal fluid is normal. In Lassa fever, nerve deafness occurs in early convalescence in 25% of cases. Prolonged convalescence is accompanied by alopecia, and in Argentine and Bolivian hemorrhagic fevers by signs of autonomic nervous system lability, such as postural hypotension, spontaneous flushing or blanching of the skin, and intermittent diaphoresis.

Laboratory studies reveal marked leukopenia, mild to moderate thrombocytopenia, proteinuria, and, in Argentine hemorrhagic fever, moderate abnormalities in blood clotting, decreased fibrinogen, increased fibrinogen split products, and elevated serum transaminases. Pathologically, there is focal, often extensive eosinophilic necrosis of liver parenchyma, focal interstitial pneumonitis, focal necrosis of the distal and collecting tubules, and partial replacement of splenic follicles by amorphous eosinophilic material. Usually bleeding occurs by diapedesis with little inflammatory reaction. The mortality rate is 10–40%.

MARBURG DISEASE AND EBOLA HEMORRHAGIC FEVER.

After an incubation period of 4–7 days, illness begins abruptly with severe frontal headache, malaise, drowsiness, lumbar myalgia, vomiting, nausea, and diarrhea. A maculopapular eruption begins 5–7 days later on the trunk and upper arms. It becomes generalized, often hemorrhagic, and exfoliates during convalescence. The exanthem is accompanied by a dark red enanthem on the hard palate, conjunctivitis, and scrotal or labial edema. Gastrointestinal hemorrhage occurs as the severity of illness increases. Late in the illness, the patient may become tearfully depressed with marked hyperalgesia to tactile stimuli. In fatal cases, patients become hypotensive, restless, and confused and lapse into coma. Convalescent patients may experience alopecia and have paresthesias of the back and trunk. There is a marked leukopenia with necrosis of granulocytes. Disseminated intravascular coagulation and thrombocytopenia are universal and correlate with severity of disease; there are moderate abnormalities in clotting proteins and elevated serum transaminases and amylase. The mortality rate of Marburg disease is 25% and of Ebola hemorrhagic fever, 50–90%.

HEMORRHAGIC FEVER WITH RENAL SYNDROME.

In most cases, HFRS is characterized by fever, petechiae, mild hemorrhagic phenomena, and mild proteinuria, followed by relatively uneventful recovery. In 20% of recognized cases, the disease may progress through four rather distinct phases. The *febrile phase* is ushered in with fever, malaise, and facial and truncal flushing. It lasts 3–8 days and ends with thrombocytopenia, petechiae, and proteinuria. The *hypotensive phase* of 1–3 days follows defervescence. Loss of fluid from the intravascular compartment may result in marked hemoconcentration. Proteinuria and ecchymoses increase. The *oliguric phase,* usually 3–5 days in duration, is characterized by a low output of protein-rich urine, increasing nitrogen retention, nausea, vomiting, and dehydration. Confusion, extreme restlessness, and hypertension are common. The *diuretic phase,* which may last for days or weeks, usually initiates clinical improvement. The kidneys show little concentrating ability, and rapid loss of fluid may result in severe dehydration and shock. Potassium and sodium depletion may be severe. Fatal cases manifest abundant protein-rich retroperitoneal edema and marked hemorrhagic necrosis of the renal medulla. The mortality rate is 5–10%.

Diagnosis.

Diagnosis depends on a high index of suspicion in endemic areas. In nonendemic areas, histories of recent travel, recent laboratory exposure, or exposure to an earlier case should evoke suspicion of a viral hemorrhagic fever.

In all viral hemorrhagic fevers, the viral agent circulates in the blood at least transiently during the early febrile stage. Togaviruses and bunyaviruses can be recovered from acute-phase serum by inoculation into tissue culture or living mosquitoes. Argentine, Bolivian, and Venezuelan hemorrhagic fever viruses can be isolated from acute-phase blood or throat washings by inoculation intracerebrally into guinea pigs, infant hamsters, or infant mice. Lassa virus may be isolated from acute-phase blood or throat washings by inoculation into tissue cultures. For Marburg disease and Ebola hemorrhagic fever, acute-phase throat washings, blood, and urine may be inoculated into tissue culture, guinea pigs, or monkeys. The viruses are readily identified by electron microscopy, with a filamentous structure differentiating them from all other known agents. Specific complement-fixing and immunofluorescent antibodies appear during convalescence. The virus of HFRS is recovered from acute-phase serum or urine by inoculation into tissue culture. A variety of antibody tests using viral subunits are becoming available. Serologic diagnosis depends on demonstrating seroconversion, or a fourfold or greater increase in immunoglobulin G antibody titer in acute and convalescent sera taken 3–4 wk apart. Viral RNA may also be detected in blood or tissues using reverse-transcriptase polymerase chain reactions.

Handling blood and other biologic specimens is hazardous and must be performed by specially trained personnel. Blood and autopsy specimens should be placed in

tightly sealed metal containers,

wrapped in absorbent material inside a sealed plastic bag, and shipped on dry ice to laboratories with biocontainment safety level 4 facilities. Even routine hematologic and biochemical tests should be done with extreme caution.

DIFFERENTIAL DIAGNOSIS.

Mild cases of hemorrhagic fever may be confused with almost any self-limited systemic bacterial or viral infection. More severe cases may suggest typhoid fever; epidemic, murine, or scrub typhus; leptospirosis; or a rickettsial spotted fever, for which effective chemotherapeutic agents are available. Many of these may be acquired in geographic or ecologic locations endemic for a viral hemorrhagic fever.

Treatment.

Ribavirin administered intravenously is effective in reducing mortality in Lassa fever and HFRS. Further information and advice about management, control measures, diagnosis, and collection of biohazardous specimens can be obtained from Centers for Disease Control and Prevention, National Center for Infectious Diseases, Special Pathogens Branch, Atlanta, Georgia 30333 (404-639-1115).

The principle involved in all these diseases, especially HFRS, is the reversal of dehydration, hemoconcentration, renal failure, and protein, electrolyte, or blood losses. The contribution of disseminated intravascular coagulopathy to the hemorrhagic manifestations is unknown, and the management of hemorrhage should be individualized. Transfusions of fresh blood and platelets are frequently given. Good results have been reported in a few patients after the administration of clotting factor concentrates. The efficacy of corticosteroids, e-aminocaproic acid, pressor amines, or a-adrenergic blocking agents has not been established. Sedatives should be selected with regard to the possibility of kidney or liver damage. The successful management of HFRS may require renal dialysis.

Prevention.

A live, attenuated vaccine (Candid-I) for Argentine hemorrhagic fever is highly efficacious. A form of inactivated mouse brain vaccine is reported to be effective in preventing Omsk hemorrhagic fever. Inactivated Rift Valley fever vaccines are widely used to protect domestic animals and laboratory workers. HFRS inactivated vaccine is licensed in Korea, and killed and live, attenuated vaccines are widely used in China. A vaccinia-vector glycoprotein vaccine provides protection against Lassa fever in monkeys. VEE replicon Ebola envelope glycoprotein and DNA-adenovirus Ebola glycoprotein vaccines have provided protection in experimental animals.

Prevention of mosquito-borne and tick-borne infections includes use of repellents, tight-fitting clothing that fully covers the extremities, careful examination of the skin after exposure with removal of any vectors found. Diseases transmitted from a rodent-infected environment can be prevented through methods of rodent control; elimination of refuse and breeding sites is particularly successful in urban and suburban areas.

Crimean-Congo hemorrhagic fever, Lassa fever, Marburg disease, and Ebola hemorrhagic fever may be transmitted in hospital settings. Patients should be isolated until they are virus-free or for 3 wk after illness. Patients' urine, sputum, blood, clothing, and bedding should be disinfected. Disposable syringes and needles should be used. Prompt and strict enforcement of barrier nursing may be lifesaving. The mortality rate among medical workers contracting these diseases is 50%. Recent studies show that a few entirely asymptomatic Ebola infections result in strong antibody production.

Chapter 249 - Lymphocytic Choriomeningitis Virus

Hal B. Jenson

Etiology.

Lymphocytic choriomeningitis virus was discovered in 1933 but not classified until the late 1960s as a member of the family Arenaviridae, which are negative-sense single-stranded RNA viruses. These enveloped viruses are round, oval, or pleomorphic, averaging 110–130?nm in diameter, with a range of 50–300?nm.

Rodents are the primary reservoir. A study in Baltimore found 9% prevalence among house mice. The virus establishes persistent infection in utero from maternal viremia that occurs in chronically infected rodents, including the common house mouse, *Mus musculus*, and pet hamsters. Their infected offspring do not develop an effective immune response and excrete virus continuously throughout life in saliva, nasal secretions, semen, milk, urine, and feces.

Epidemiology.

The virus has been found in temperate regions of Europe and the Americas. The epidemiology of rodent infection is highly focal. Human cases are sporadic and are least common during the summer. Outbreaks have been reported after exposure to infected pet hamsters. A serologic survey of adults attending a sexually transmitted disease clinic in Baltimore found that 4.7% of adults had evidence of past infection.

Transmission from rodents to humans is by aerosol, by direct contact with rodents or contaminated food and fluids, and infrequently by rodent bites. There is no evidence of chronic infection in humans or of person-to-person transmission.

Pathogenesis.

Viral infection of rodents is chronic and appears to lead to chronic glomerulonephritis. After inhalation of virus by humans, there is pulmonary and hilar lymph node viral replication with viremia within 48?hr. The liver, spleen, and lymph nodes are most affected and show lymphoid hyperplasia. The kidneys, heart, skeletal muscle, epididymis, and other organs may show mononuclear infiltration.

Clinical Manifestations.

Infection in humans is inapparent in approximately one third of cases. Symptomatic cases may include a nonspecific flulike illness that is unrecognized as lymphocytic choriomeningitis virus infection, or may be characterized by lymphocytic meningitis or meningoencephalitis of varying severity. The classic course is a biphasic illness with usually 3–5 days of nonspecific illness with fever, malaise, myalgias, nausea and vomiting, sore throat and cough, lymphadenopathy, and occasionally a maculopapular rash. There is defervescence for 2–4 days followed by recurrence of fever and headache. In a small proportion of patients, signs of meningoencephalitis develop,

---

sometimes without the prodromal symptoms. The cerebrospinal fluid pressure is elevated, and shows elevated protein (50–300?mg/ dL) with several hundred lymphocytes per microliter. There may be papilledema. Transverse myelitis has also been reported. Extraneural manifestations include arthritis, parotitis, orchitis, rash, and myocarditis.

Leukopenia and thrombocytopenia are typical. There are no associated bleeding diatheses, as occur with other arenaviruses (Junin, Machupo, Guanarito, and Lassa) that are associated with viral hemorrhagic fevers (Chapter 248).

CONGENITAL INFECTION.

Approximately 32 cases of congenital lymphocytic choriomeningitis virus infection have been reported. Only one half of mothers relate illnesses compatible with lymphocytic choriomeningitis virus during pregnancy, usually with only flulike symptoms but occasionally compatible with aseptic meningitis. Only one fourth of mothers have known exposure to rodents.

The affected offspring typically have chorioretinitis, encephalomalacia, microcephaly, hydrocephalus, punctate intracranial calcifications, and developmental delay. The neonatal presentation is similar to congenital cytomegalovirus and toxoplasmosis, but typically without hepatosplenomegaly, and should be considered if there is a history of maternal rodent exposure. Other ophthalmologic manifestations may include optic atrophy, microphthalmia, vitreitis, leukokoria, and cataracts. Unlike congenital cytomegalovirus infection, hearing loss has not been reported.

The cerebrospinal fluid shows a mild pleocytosis (<70 white blood cells/μL) and mildly elevated protein (average of 67?mg/dL; range of 9–477?mg/dL). CT and MRI reveal encephalomalacia, ventricular enlargement, and calcifications (by CT) adjacent to the lateral ventricles or in the periventricular white matter.

Diagnosis.

The diagnosis is usually suspected by the clinical manifestations after exposure to rodents. Serologic tests using immunofluorescent antibody and enzyme-linked immunosorbent assay methods can confirm the clinical diagnosis. The virus can also be isolated from the blood and cerebrospinal fluid during the first week of illness.

Treatment.

There is no specific treatment for lymphocytic choriomeningitis virus. Ribavirin is active against lymphocytic choriomeningitis virus and other arenaviruses in vitro. Supportive care includes headache control and intravenous hydration, if necessary.

Prognosis.

The illness is usually self-limited without sequelae. Hydrocephalus, probably resulting from arachnoidal and ependymal inflammation, is a characteristic complication of congenital infection and has been reported rarely after lymphocytic choriomeningitis virus infection in older children and adults.

Prevention.

Minimizing direct contact with the rodent hosts, especially excreta, is the best means of prevention. This precaution is especially important for pregnant women and should be emphasized. The prevalence of lymphocytic choriomeningitis virus in laboratory animals and household pets, primarily hamsters, is variable and depends on the breeding and handling conditions. Routine monitoring of rodents for infection is not uniformly practiced or mandated.

Chapter 250 - Hantaviruses

Scott B. Halstead

In June 1993, a newly recognized hantavirus was identified as the etiologic agent of an outbreak of severe respiratory illness in the southwestern United States. Now called the **hantavirus pulmonary syndrome (HPS)**, hundreds of cases caused by multiple closely related hantaviruses have been identified from the Western United States, with sporadic cases reported from Eastern United States, Canada, and several countries in South America. HPS is characterized by a febrile prodrome followed by the rapid onset of noncardiogenic pulmonary edema and hypotension or shock. More than half of patients diagnosed with HPS have died.

Etiology.

Hantaviruses are a genus in the family Bunyaviridae, which are lipid-enveloped viruses with a negative-stranded RNA genome composed of three unique segments. Several pathogenic viruses that have been recognized within the genus include **Hantaan virus,** which causes the most severe form of hemorrhagic fever with renal syndrome (HFRS) seen primarily in mainland Asia; **Dobrava virus,** which causes the most severe form of HFRS seen primarily in the Balkans; **Puumala virus,** which causes a milder form of HFRS with a high proportion of subclinical infections and is prevalent in northern Europe; and **Seoul virus,** which results in moderate HFRS and is transmitted predominantly in Asia by urban rats or worldwide by laboratory rats. **Prospect Hill virus,** a Hantavirus that is widely disseminated in U.S. meadow voles, is not known to cause human disease.

Cases of HPS identified in 1993 were associated with **Sin Nombre virus**, isolated from deer mice, *Peromyscus maniculatus*, in New Mexico. Multiple HPS agents isolated to date belong to a single genetic group of hantaviruses and are associated with rodents of the family *Muridae*, subfamily *Sigmodontinae*. These rodent species are restricted to the Americas, suggesting that HPS may be a Western Hemisphere disease.

Epidemiology.

Persons acquiring HPS generally have a history of recent outdoor exposure or live in an area with large populations of deer mice. Clusters of cases have occurred among

individuals who have cleaned houses that were rodent infested. *P. maniculatus* is one of the most common North American mammals and, where found, is frequently the dominant member of the rodent community. About half of cases occur between the months of May and July. Patients are almost exclusively from 12–70 yr of age; 60% of patients are 20–39 yr of age. Rare cases are reported in children <12 yr of age. Two thirds of patients are male, probably reflecting greater outdoor activities. It is not known whether almost complete absence of disease in young children is a reflection of innate resistance or simply lack of exposure. Evidence of human transmission has been obtained in Argentine outbreaks.

Hantaviruses do not cause apparent illness in their reservoir hosts, which remain asymptomatically infected for life. Infected rodents shed virus in saliva, urine, and feces for many weeks,

but the duration of shedding and the period of maximum infectivity are unknown. The presence of infectious virus in saliva, the sensitivity of these animals to parenteral inoculation with hantaviruses, and field observations of infected rodents indicate that biting is important for rodent-to-rodent transmission. Aerosols from infective saliva or excreta of rodents are implicated in the transmission of hantaviruses to humans. Persons visiting animal care areas housing infected rodents have been infected after exposure for as little as 5?min. It is possible that hantaviruses are spread through contaminated food and breaks in skin or mucous membranes; transmission to humans has occurred by rodent bites. Person-to-person transmission is distinctly uncommon but has been documented in Argentina.

Pathogenesis.

HPS is characterized by sudden and catastrophic pulmonary edema, resulting in anoxia and acute heart failure. The virus is detected in pulmonary capillaries, suggesting that pulmonary edema is the direct consequence of virus-induced capillary damage. Disease severity is predicted by level of acute phase viremia titer.

Clinical Manifestations.

HPS is characterized by a prodrome and a cardiopulmonary phase. The mean duration after the onset of prodromal symptoms to hospitalization is 5.4 days. The mean duration of symptoms to death is 8 days (median of 7 days; range of 2–16 days). The most common prodromal symptoms are fever and myalgia (100%); cough or dyspnea (76%); gastrointestinal symptoms, including vomiting, diarrhea, and midabdominal pain (76%); and headache (71%). The cardiopulmonary phase is heralded by progressive cough and shortness of breath. The most common initial physical findings are tachypnea (100%), tachycardia (94%), and hypotension (50%). Rapidly progressive acute pulmonary edema, anoxemia, and shock develop in most severely ill patients. The clinical course of the illness in patients who die is characterized by pulmonary edema accompanied by severe hypotension, frequently terminating in sinus bradycardia, electromechanical dissociation, ventricular tachycardia, or fibrillation. Hypotension may be progressive even with adequate oxygenation.

Diagnosis.

The diagnosis of HPS should be considered in a previously healthy patient presenting with a febrile prodrome and acute respiratory distress. Occurrence of thrombocytopenia with the febrile prodrome and outdoor exposure in the spring and summer months are strongly suggestive of HPS. Specific diagnosis of HPS is made by serologic tests that detect hantavirus immunoglobulin M antibodies. Hantavirus antigen can be detected in tissue by immunohistochemistry and amplification of hantavirus nucleotide sequences detected by reverse transcriptase polymerase chain reaction. The state health department or the Centers for Disease Control and Prevention should be consulted to assist in diagnosis, epidemiologic investigations, and outbreak control.

LABORATORY FINDINGS.

Laboratory findings include leukocytosis (median of 26,000 cells/µL), an increased hematocrit (resulting from hemoconcentration), thrombocytopenia (median of 64,000/µL), prolonged prothrombin and partial thromboplastin times, elevated serum lactate dehydrogenase concentration, decreased serum protein concentrations, and proteinuria.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis includes adult respiratory distress syndrome, pneumonic plague, psittacosis, severe mycoplasmal pneumonia, influenza, leptospirosis, inhalation anthrax, rickettsial infections, pulmonary tularemia, atypical bacterial and viral pneumoniae, legionellosis, meningococcemia, and other sepsis syndromes.

Treatment.

Management of patients with hantavirus infection requires maintenance of adequate oxygenation and careful monitoring and support of cardiovascular function. The pathophysiology of HPS resembles that of dengue shock syndrome (Chapter 246). Pressor or inotropic agents should be administered in combination with judicious volume replacement to treat symptomatic hypotension or shock while avoiding exacerbating the pulmonary edema. Intravenous ribavirin, which is lifesaving if given early in the course of HFRS, has been shown to be of no value in HPS.

Further information and advice about management, control measures, diagnosis, and collection of biohazardous specimens can be obtained from Centers for Disease Control and Prevention, National Center for Infectious Diseases, Special Pathogens Branch, Atlanta, Georgia 30333 (404-639-1115).

Prognosis.

Patient fatality rates are about 50%. Severe abnormalities in hematocrit, white blood cell count, lactate dehydrogenase, and partial thromboplastin time predict mortality

with high specificity and sensitivity.

Prevention.

Avoiding contact with rodents is the only preventive strategy. Rodent control in and around the home is important. Biosafety level 2 facilities and practices are recommended for laboratory handling of blood, body fluids, and tissues from suspect patients or rodents because the virus may be aerosolized. Barrier nursing is advised.

Chapter 251 - Rabies

William G. Adams

Human rabies is a viral infection of the central nervous system usually transmitted by contamination of a wound with saliva from a rabid animal. Rabies transmission can be prevented with postexposure prophylaxis; however, the disease is virtually 100% fatal once symptoms develop.

Etiology.

Rabies virus is a member of the family Rhabdoviridae. Rabies and several closely related rabies-like viruses are classified in the genus *Lyssavirus*. Rabies-related viruses are found in Europe and Africa and are relatively rare. The viral particles resemble striated bullets, 70–85?nm in diameter and 130–380?nm in length. They have a lipid-containing envelope with a helical nucleocapsid containing one molecule of the negative-sense single-stranded RNA genome. The envelope contains a glycoprotein that elicits neutralizing antibodies and acts as a protective antigen in animal experiments.

Epidemiology.

Rabies infection occurs in warm-blooded animals throughout the world. In the United States, rabies occurs principally in skunks, raccoons, foxes, and bats. Skunks are the principal vectors in the Midwest, Southwest, and California,

with distinct northern and southern virus strains. Raccoon rabies is found throughout the eastern United States. Fox rabies is found in Alaska and the northeastern United States, with a separate strain in the Southwest. Bat rabies is found in practically every state. In Central and South America, dogs are the usual source of exposure. Vampire bats, which bite cattle, are an important part of the cycle of rabies in Latin America. Europe has had an epizootic of fox rabies. In Asia and Africa, the principal problem is the rabid dog.

Monoclonal antibody analysis and reverse transcriptase(RT) followed by polymerase

chain reaction (PCR) of rabies virus strains has revealed considerable antigenic variation of the virus. The result has been the identification of variant strains, called **rabies-related viruses**, and antigenic differences among true rabies viruses that correlate with host species or geographic location. Strains isolated from cattle rabies in South America resemble bat strains, confirming the transmission of virus from the vampire bat to the cow.

The existence of rabies-free land areas permits health authorities in certain locations to omit postexposure prophylaxis of humans after most dog bites on the grounds that terrestrial rabies has been unknown there for years. The continent of Australia and many islands, including those of the United Kingdom and Hawaii, are free of rabies.

Human rabies is a rare disease in the United States and western Europe, where domestic animals are routinely vaccinated and animal control efforts have been successful. Most human cases in these areas are imported from other countries or follow bat exposure. Rabies continues to be a major public health problem in areas where dogs are not controlled. Human rabies occurs routinely in India, Southeast Asia, and Africa. The annual global incidence of human rabies is unknown, but is likely between 40,000–100,000 cases. Children are at particularly high risk for rabies exposure and infection because of their shorter stature, fearlessness of animals, and inability to protect themselves.

TRANSMISSION.

In animals, as in humans, rabies produces encephalitis as the principal symptom followed by spread of virus down nerves away from the brain. It multiplies in many organs, but those most important to transmission are the salivary glands. However, not all rabid animals have virus in the saliva, and even when it is present, the quantity is variable. The incubation period for rabies in infected dogs is variable, from 14–180 days. However, viral shedding in saliva of dogs occurs for only 3–6 days before visible symptoms begin. Rabies transmission to humans from dogs that appeared normal for =10 days after a biting incident has not been reported. The variability of virus in saliva explains the low transmissibility; less than half of untreated bites by proven rabid animals result in rabies.

Transmission of rabies can also occur from nonbite exposures. Scratches by the claws of rabid animals are dangerous because animals lick their claws. Saliva applied to a mucosal surface such as the conjunctiva may be infectious. Furthermore, several cases of human rabies in the United States appear to have been caused by bats without any visible sign of direct contact. Bat excreta contain enough rabies virus to pose a danger of rabies to those who enter infested caves and inhale aerosols created by bats or with insignificant physical contact. Aerosols of rabies virus inadvertently produced in laboratories are dangerous to laboratory workers. Transmission of rabies by corneal transplant from patients with undiagnosed rabies encephalitis to healthy recipients has been recorded with sufficient frequency to warrant exclusion of donors dead from unexplained neurologic disease. Human-to-human transmission is theoretically possible but is poorly documented and occurs rarely, if at all.

Pathogenesis.

The means by which rabies virus travels from the wound to the brain are only partially understood. Because the virus attaches to and penetrates cells rapidly in vitro, it is unlikely that it remains dormant in the wound for long periods of time. Although the virus ascends along axons from the distal extremities to the spinal cord, the speed of spread (3?mm/hr) is far too rapid to account for the long incubation period of the disease.

After inoculation with contaminated saliva from a bite or scratch, the virus infects and multiplies in striated muscle cells, to which it attaches via several receptors, probably including the nicotinic acetylcholine receptor. It is hypothesized that antibody, interferon, and other host factors act on the virus as it leaves striated muscle; if these factors are insufficiently protective, virus eventually attaches to the nerve. At this stage, the development of rabies may be inevitable. The possibility that the virus must overcome another barrier in passing from the first infected neuron to other neurons is indicated by electron microscopic studies of the brain, which demonstrate contiguous viral passage from cell to cell.

Rabies virus causes neuronal destruction in the brainstem and medulla. The cerebral cortex is usually normal in the absence of prolonged anoxia before death. The hippocampus, thalamus, and basal ganglia often show neuronal destruction and glial infiltrates. The most severe disease is evident in the pons and the floor of the fourth ventricle. The inspiratory muscle spasms that result in the striking symptom of hydrophobia may be due to destruction of brainstem neurons inhibitory to the neurons of the nucleus ambiguus, which control inspiration. Hydrophobia does not occur in other diseases because only rabies combines brainstem encephalitis with an intact cortex and maintenance of consciousness.

The **Negri body**, long the pathologic hallmark of rabies, is a cytoplasmic inclusion found in neurons; it consists of clumped viral nucleocapsid. The absence of Negri bodies does not exclude rabies; fluorescent antibody stains of brain sections or smears may be positive in their absence.

Clinical Manifestations.

The incubation period of rabies in humans is extremely variable. Exceptionally long incubation periods have been described, including a 7-yr incubation period that was confirmed by strain identification. Conversely, an incubation period of as little as 9 days has followed severe exposure. Usually, the incubation period is 20–180 days, with the peak at 30–60 days. The incubation period tends to be shorter in children.

There is usually a prodromal phase of rabies lasting 2–10 days. Pain, pruritus, or paresthesia at the site of the wound is common. Nonspecific symptoms such as fever, malaise, headache, anorexia, and vomiting are often seen. The patient may also have apprehension, anxiety, agitation, or depression.

The illness then enters an acute neurologic phase, of either the **furious variety** or **paralytic variety**, which lasts 2–21 days. In the former, **hydrophobia** is a pathognomonic sign. Attempts to swallow liquids, including saliva, result in aspiration into the trachea. Hydrophobia appears to be an exaggerated respiratory tract protective reflex, perhaps mediated by neuronal dysfunction in the brainstem.

Eventually, a psychological component exacerbates the spasms, and even the sight of water evokes terror. **Aerophobia** may be present and is considered by some also to be pathognomonic of rabies. Aerophobia is elicited by fanning a current of air across the face, which causes violent spasms of the pharyngeal and neck muscles.

The neurologic picture in the typical case may consist of bursts of hyperactivity, disorientation, and bizarre combative behavior, alternating with periods of lucidity. During the lucid periods, the patient may be aware of what is happening and may be able to articulate his or her fears. The facial expression is one of grim hopelessness. Patients may also complain of pharyngeal pain, difficulty in swallowing, and hoarseness. Seizures are common, perhaps on the basis of hypoxia compounded by hyperventilation.

In about 20% of patients, an ascending symmetric paralysis with flaccidity and decreased tendon reflexes dominates the entire acute phase. This course is particularly common after bat

---

bites. In the remainder of patients, paralysis develops toward the end of the acute neurologic phase.

Some rabid patients experience meningism or even opisthotonos. The cerebrospinal fluid may be normal or may reflect meningeal irritation, with varying elevations of cells (predominantly lymphocytes) and protein. The peripheral white blood cell count often shows a polymorphonuclear leukocytosis.

If the patient does not die of cardiorespiratory arrest during the acute stage, coma ensues. With modern intensive care, life may be prolonged, but numerous complications occur during this stage. Most significant is myocarditis, manifested by hypotension and arrhythmias. Rabies virus has been recovered from the heart, which shows inflammation at autopsy. Also prominent is pituitary dysfunction expressed clinically as either diabetes insipidus or inappropriate secretion of antidiuretic hormone.

Humans infected with rabies are infectious for about 1 wk before onset of symptoms and can continue to be infectious for up to 5 wk afterward.

Diagnosis.

Rabies should be suspected in patients with a history of an animal bite or proximity to bats, especially involving wounds complicated by paresthesia or dysesthesia surrounding the wound site, central nervous system changes, hydrophobia, or aerophobia.

Laboratory diagnosis is possible before death. The virus may be demonstrated by fluorescent antibody stain or reverse-transcriptase polymerase chain reaction (RT-PCR) of smears of corneal epithelial cells or sections of skin from the neck at the hairline. These are sensitive tests because virus migrates down the nerves from the brain, and both the cornea and hair follicles are richly innervated. Virus can also be isolated or identified in saliva. Autopsy examination of the brains of patients with fatal encephalitis should include fluorescent antibody test or RT-PCR for rabies.

Serologic diagnosis is also possible if the patient survives beyond the acute period. Neutralizing antibodies develop eventually in both serum and cerebrospinal fluid and rapidly increase to extremely high levels, usually more than 100?IU/mL. Vaccination, even with potent vaccine, is unlikely to raise titers above 20?IU/mL.

DIFFERENTIAL DIAGNOSIS.

Any disease in which there is encephalitis may occasionally cause mental status changes and confusion, such as the encephalitides caused by arboviruses, enteroviruses, and herpes simplex. Other diagnoses can usually be set aside with signs of brainstem involvement in a patient whose sensorium is basically clear and who has no signs of a space-occupying lesion. Paralytic rabies may be misdiagnosed as Guillain-Barré syndrome, poliomyelitis, or postrabies vaccine encephalomyelitis. Careful neurologic examination and analysis of the cerebrospinal fluid distinguish these diagnoses. The spasms of tetanus may represent a diagnostic dilemma, but trismus is not seen in rabies, and hydrophobia is not seen in tetanus. Botulism (wound or ingestion) causes paralysis, but the absence of sensorineural changes excludes rabies. Perhaps the most confusing differential problem is hysteria in an individual who thinks that he or she has rabies. Normal blood gases and the absence of variation in bizarre behavior suggest pseudorabies.

Treatment.

There is no specific treatment available. Intensive supportive care is often required but is insufficient for recovery. Therapies with antiviral agents, interferon, and high-dose rabies immunoglobulin have only prolonged the clinical course. It is doubtful that any treatment can affect mortality once the virus has already spread to the brain.

Prognosis.

Recovery from symptomatic rabies in humans is extremely rare. Several persons in the United States have survived rabies infection, but all appear to have been partially immunized before exposure.

Prevention.

Primary prevention of rabies infection includes avoiding contact with potentially rabid animals and vaccination of all domestic animals. Special efforts should be made to teach children to avoid wild animals, stray animals, and animals with unusual behavior.

LOCAL WOUND CARE.

Regardless of the decision whether to provide immunoprophylaxis, local wound management after exposure to a potentially rabid animal is important. All

postexposure treatment begins with immediate thorough cleansing of all wounds with soap and water. Vigorous cleansing has been shown to effectively prevent infection in countries with endemic rabies. Wounds should be irrigated for at least 10?min, preferably with a virucidal agent such as povidone-iodine. Catheters should be used for irrigation of puncture wounds. If the mechanical trauma of the local treatment is painful, local anesthetics (e.g., lidocaine) may be used to infiltrate the area without adding risk.

EVALUATION OF EXPOSURES.

Human exposure to a potentially rabid animal is considered to be present if the person (1) is bitten or scratched (with penetration of skin) by a potentially rabid animal or (2) has contamination of a scratch, abrasion, mucous membranes, or open wound with potentially infectious material such as saliva or central nervous system tissue from a potentially rabid animal. The evaluation of human exposures to potentially rabid animals can be complex and is often compounded by a high degree of anxiety. The decision to give postexposure rabies prophylaxis should be based on several factors (Table 251–1). The local epidemiology of rabies should be considered. The type of animal is important because some animals such as raccoons, skunks, bats, woodchucks, and unvaccinated domestic animals are more likely to be infected with

TABLE 251-1 -- **Rabies Postexposure Prophylaxis Guide for the United States**

Animal	Evaluation and Disposition of Animal	Postexposure Prophylaxis Recommendations
Dogs, cats, ferrets	Healthy and available for 10-day observation	Should not begin prophylaxis unless signs of rabies develop in animal[*]
	Rabid or suspected rabid	Immediately vaccinate
	Unknown (e.g., escaped)	Consult public health officials
Skunks, racoons, foxes, most other carnivores; bats	Regarded as rabid unless animal proven negative by laboratory tests[†]	Consider immediate vaccination
Livestock, small rodents, lagomorphs (rabbits and hares), large rodents (woodchucks and beavers), other mammals	Consider individually	Consult public health officials; bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, other small rodents, rabbits, and hares almost never require antirabies prophylaxis

Modified from Centers for Disease Control: Human rabies prevention-United States, 1999. Recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR 1999;48(RR-1):1–21.

**During the 10-day holding period, begin postexposure prophylaxis with human rabies immune globulin (HRIG) and rabies vaccine (HDCV, PCEC, or RVA) at first sign of rabies in a dog or cat that has bitten someone. If the animal exhibits clinical signs of rabies, it should be euthanized immediately and tested.*

† The animal should be euthanized and tested as soon as possible. Holding for observation is not recommended. Discontinue vaccine if immunofluorescence test results of the animal are negative.

rabies virus in certain areas than other animals, such as vaccinated dogs and cats or small wild animals such as squirrels or rodents. The availability of the responsible animal for testing or quarantine is an important consideration and can determine whether or not postexposure prophylaxis is necessary. The circumstances around the exposure, namely whether the attack was provoked or unprovoked, can be considered, especially in situations involving animals rarely infected with rabies virus such as squirrels or mice.

Postexposure rabies prophylaxis is indicated for all persons with a history of a bat bite, scratch, or mucous membrane exposure unless the bat is available for testing and is negative for evidence of rabies. Postexposure prophylaxis is appropriate after bat exposure even in the absence of known direct contact, when there is a reasonable probability that such contact occurred, such as when a sleeping person awakes to find a bat in the room or when an adult witnesses a bat in the room with a previously unattended child, mentally disabled person, or intoxicated person.

Evaluation of secondary or indirect exposure can be more difficult than the evaluation of the direct exposures outlined previously. Secondary contact is typically considered to occur when a domestic animal has had direct contact with a potentially rabid animal and a human then handles or is licked by the domestic animal. The factors that should be considered include the interval since the pet's exposure, the ambient temperature, and whether the domestic animal's contact with the human involved an open wound or mucous membranes.

POSTEXPOSURE PROPHYLAXIS.

If rabies prophylaxis is to be given after exposure, prevention depends on three complementary means of reducing the risk. Local wound care is designed to remove or kill the virus by mechanical and virucidal action. Passive immunization with human rabies immunoglobulin (HRIG) then provides immediate blockage of attachment of virus to the nerve endings. However, passive antibody ultimately disappears and must be replaced by the active immune response induced by vaccine. The vaccine must not only produce a primary antibody response but also overcome the depressive effect of passive antibody on the immune response. When given according to currently recommended protocols, no failure of combined HRIG and

approved rabies vaccine has been reported in the United States.

Passive Immunization.

Passive antibody is available as HRIG; the two available formulations are considered equivalent. The dose for HRIG is 20?IU/kg with as much as possible of the full dose of HRIG thoroughly infiltrated into and around the wounds. Any remaining volume should be administered intramuscularly at a site distant from vaccine inoculation. In some countries, rabies antibody is in the form of purified equine immunoglobulin, which is associated with serum sickness reactions in about 1% of recipients. Anaphylaxis is a rare possibility with the equine product, but tests for hypersensitivity should be carried out in the usual manner (consult package insert). The dose for equine immunoglobulin is 40?IU/kg delivered in the same manner as for HRIG.

HRIG is effective if given within 7 days of the bite and ideally should be given with rabies vaccine on the day of the exposure. If vaccine was started previously, passive immunization should not be given after 7 days have elapsed. Corticosteroids should be avoided if possible in the treatment of reactions because they cause activation of rabies virus in experimental animals.

Active Immunization.

Early rabies vaccines were prepared in the central nervous systems of animals. Their antigenicity was poor, and multiple injections were required. As a result, postvaccination encephalitis was a frequent problem. Animal nerve tissue vaccines are still in use in many places in the world, in particular, suckling mouse brain vaccine, which gives fewer neurologic reactions than sheep brain vaccines because it contains less myelin.

The major advance in rabies vaccine was the development of cell culture technology, which permitted the production of concentrated vaccines with high antigenic potency and low contamination with cellular proteins. Thus, immunogenicity was improved, allowing reduced numbers of doses and adverse reactions. Two cell culture rabies vaccines are available in the United States: **human diploid cell vaccine (HDCV)** and **purified chick embryo cell culture vaccine (PCECV)**. Outside the United States, vaccines produced in monkey kidney, chick embryo, duck embryo, and other cultured cells are also available.

For previously unvaccinated persons, the schedule for postexposure vaccination is five doses given intramuscularly in the deltoid on days 0, 3, 7, 14, and 28. The dose is not reduced for children, although the anterolateral thigh can be used instead of the deltoid if necessary. Administration of rabies vaccine in the gluteus muscle has been associated with vaccine failure and is to be avoided. Immune responses to the postexposure schedule are regularly seen by the 14th day. However, for effective postexposure prophylaxis to rabies, it is mandatory to provide passive as well as active immunization.

For previously fully vaccinated persons after rabies exposure, two vaccine doses are given at an interval of 3 days. HRIG is not given.

Determination of postvaccination antibody titers is not needed unless the patient is immunosuppressed or is receiving antimalarial therapy, which may suppress the response.

Adverse reaction rates to cell culture vaccines have been low, and neurologic reactions have been rare because no nerve tissue is present in the cell cultures used to grow the virus. Allergic reactions occur in less than 0.1% of cases after primary vaccination with HDCV, and systemic symptoms such as malaise and fever occur in only 5–15%. Administration of boosters is associated with an allergic reaction rate of up to 6%. Individuals at continued risk of rabies exposure should have antibody titers determined every 2 yr, and if inadequate, should be given a booster dose. PCECV may be useful in those who have reactions to HDCV. Although no controlled study has been done, the efficacy of rabies vaccination is evidently high, judging from the known incidence of disease after untreated bites by infected animals (approximately 15%) and the paucity of vaccine failures. When seen, vaccine failure has usually followed incomplete immunizations schedules or incorrect use of HRIG.

PREEXPOSURE PROPHYLAXIS.

Persons at risk for rabies, such as veterinarians, laboratory workers, spelunkers, and travelers to rabies-enzootic areas, should be immunized before exposure. For preexposure immunization, a three-dose vaccination schedule is followed, consisting of intramuscular doses (1.0?mL) given on days 0, 7, and 21 or 28.

Chapter 252 - Polyomaviruses

Hal B. Jenson

The polyomaviruses, which with the papillomaviruses constitute the Papovaviridae family, are small, nonenveloped, double-stranded circular DNA viruses. The two polyomaviruses that infect humans, JC virus and BK virus, share 75% genome homology but are antigenically distinct. Both viruses are tropic for renal epithelium; JC virus also infects brain oligodendrocytes and is the etiologic agent of **progressive multifocal leukoencephalopathy (PML)**, a fatal demyelinating disease. Several million persons in the United States were exposed to simian virus 40, an oncogenic polyomavirus of Asian macaques, from contaminated inactivated poliovirus vaccines administered between 1955 and 1963, without recognized sequelae and with no demonstrable increased risk of cancer.

Approximately one half of children in the United States are infected with BK virus by 3–4 yr of age and with JC virus by 10–14 yr of age, and approximately 60–80% of adults are seropositive for one or both viruses. Infection persists throughout life, with the viruses remaining latent in renal epithelium, oligodendrocytes, and peripheral blood lymphocytes. Reactivation and viruria occur with increased frequency with advancing age and are more common in immunocompromised persons. BK and JC viruria, as detected by polymerase chain reaction (PCR), occurs in 2.6% and 13.2%, respectively, of persons <30 yr of age and in approximately 9% and 50%, respectively, of persons >60 yr of age.

Reactivation of BK virus and JC virus with asymptomatic viruria occurs in 10–50% of bone marrow transplant patients and in 20% of renal transplant patients. The direct cytopathic effect of reactivated BK virus on donor ureter has caused localized ureteral ulceration and ureteral stenosis in a few renal transplant patients. BK virus has also been associated with prolonged hemorrhagic cystitis in bone marrow transplant recipients.

PML is a rare central nervous system demyelinating disease resulting from viral lytic infection of myelin-producing oligodendrocytes and an abortive infection of astrocytes. It occurs almost exclusively in immunocompromised persons. More than one half of cases occur in HIV-infected persons, and PML is found in approximately

5% of autopsied AIDS patients. PML characteristically presents with motor weakness, visual field deficits (typically a homonymous hemianopsia), and speech and cognitive impairment (dementia, confusion, personality change). Less frequent symptoms include ataxia, cranial nerve deficits, and extrapyramidal symptoms. The brain shows multifocal, asymmetric, coalescing focal demyelination of white matter with a characteristic cytologic appearance of hyperchromatic enlarged oligodendroglial nuclei and bizarre astrocytes with enlarged multilobulated nuclei. The lesions on CT scan appear as hypodense, nonenhancing focal lesions without surrounding edema or inflammation. On MRI the lesions are hyperintense on T2 weighted images. The cerebrospinal fluid (CSF) is typically normal, but may show mild elevation of protein and less frequently a mononuclear pleocytosis, usually less than 25 cells/μL. JC virus DNA may be detected by PCR in the CSF. Confirmation of the diagnosis requires brain biopsy for histopathologic examination. Patients rapidly experience severe neurologic deficits, including cortical blindness and quadriparesis, with death ensuing usually within 6 months of initial presentation. There is no specific treatment.

Polyomavirus sequences have been identified in human tumors, including osteosarcomas, mesotheliomas, and brain tumors (ependymomas, glioblastomas, oligodendrogliomas, and others). The etiologic role of these viruses in human oncogenesis remains uncertain.

Chapter 253 - Transmissible Spongiform Encephalopathies*

David M. Asher

The transmissible spongiform encephalopathies (TSEs) are slow infections of the human nervous system, consisting of at least four diseases of humans (Table 253–1): kuru; Creutzfeldt-Jakob disease (CJD) with its variants—**sporadic CJD (sCJD)**, **familial CJD (fCJD)**, **iatrogenic CJD (iCJD)**, and **new-variant or variant CJD (vCJD); Gerstmann—Sträussler-Scheinker syndrome (GSS)**; and **fatal familial insomnia (FFI),** or the even more rare **sporadic fatal insomnia syndrome**. TSEs also affect animals; the most common and best-known TSEs of animals are **scrapie** in sheep, **bovine spongiform encephalopathy (BSE or "mad cow disease")** in cattle, and a **chronic wasting disease (CWD)** of deer and elk found in parts of the United States and Canada. All TSEs have similar clinical manifestations and histopathology, and all are "slow" infections with very long asymptomatic incubation periods of at least a year, durations of several months or more, and overt disease (although not infection) restricted to the nervous system. The most striking neuropathologic change that occurs in each TSE, to a greater or lesser extent, is spongy degeneration of the cerebral cortical gray matter.

Etiology.

The TSEs are all transmissible to susceptible animals by inoculation of tissues from affected subjects. Although the infectious agents replicate in some cell cultures, they do not achieve the high titers of infectivity found in brain tissues or cause recognizable cytopathic effects in cultures. Most studies of TSE agents have used in vivo assays, using the appearance of typical neurologic disease in animals as evidence that the agent was present and intact. Inoculation of susceptible recipient animals with small amounts of infectious TSE agent results, months later, in the accumulation in tissues of large amounts of agent with the same physical and biologic properties as the original agent. The TSE agents display a spectrum of extreme resistance to inactivation by a variety of chemical and physical treatments that is unknown among conventional pathogens. This characteristic, as well as their partial sensitivity to protein-disrupting treatments and their consistent association with an abnormal amyloid protein stimulated the hypothesis that the TSE agents are probably subviral in size, composed of protein, and devoid of nucleic acid.

In 1982, S. B. Prusiner suggested the term **prion** (for proteinaceous infectious agent) as an appropriate name for such

*All material in this chapter is in the public domain, with the exception of any borrowed figures or tables.

TABLE 253-1 -- **Transmissible Spongiform Encephalopathies (TSEs; Prion Diseases) of Humans and Animals**

Disease	**Naturally Infected Hosts**

Chronic wasting disease	American, Canadian deer, elk
Scrapie	Sheep, goats
Transmissible mink encephalopathy	Mink

agents. The prion hypothesis, in its most recent form, proposes that the molecular mechanism by which the pathogen-specific information of TSE agents is propagated involves a self-replicating change in the folding of a host-encoded protein associated with a transition from an a-helix–rich structure in the native protease-sensitive conformation to a ß-sheet–rich structure in the protease-resistant conformation associated with infectivity. The existence of a second host-encoded protein—termed "protein X"—that participates in the transformation was also postulated to explain certain otherwise puzzling findings.

The prion hypothesis has been widely accepted and was recognized by the awarding of the Nobel Prize in physiology and medicine to Prusiner in 1997. However, the prion hypothesis has not been universally accepted; it relies on the postulated existence of a genome-like coding mechanism based on differences in protein folding that have not been satisfactorily explained at a molecular level. In addition, it has yet to account for the many biologic strains of TSE agent that have been observed, although strain-specific differences in the abnormal forms of the prion protein (PrP) have been found and proposed as providing a molecular basis for the coding. It fails to explain why pure PrP uncontaminated with nucleic acid from an uninfected host has not transmitted a typical spongiform encephalopathy associated with a serially self-propagating agent. If the TSE agents ultimately prove to consist of protein and only protein, without any nucleic acid component, then the term prion will indeed be appropriate. If the agents are ultimately found to contain small nucleic acid genomes, then they might better be considered atypical viruses for which the term **virino** has been suggested. Until the actual molecular structure of the infectious TSE pathogens and the presence or absence of a nucleic acid genome are rigorously established, it seems less contentious to continue calling them TSE agents.

The first evidence that abnormal proteins are associated with the TSE was morphologic: **Scrapie-associated fibrils (SAFs)** were found in extracts of tissues from a variety of patients and animals with spongiform encephalopathies but not in normal tissues. SAFs resemble but are distinguishable from the amyloid fibrils that accumulate in the brains of patients with Alzheimer disease. A group of antigenically related, protease-resistant proteins, now designated **PrP^{Sc} (scrapie-type prion protein) or PrP-res (protease-resistant prion protein)**, proved to be components of SAF and to be present in the amyloid plaques found in the brains of patients and animals with TSE.

It is not yet clear whether abnormal PrP constitutes the complete infectious particle of spongiform encephalopathies or a component of those particles, or is simply a pathologic host protein not usually separated from the actual infectious entity by currently used techniques. The demonstration that PrP is encoded by a normal host gene seemed to favor the last possibility. However, several studies have suggested that agent-specific pathogenic information can be transmitted and replicated by different conformations of a protein with the same primary amino acid sequence in the absence of agent-specific nucleic acids. (Properties of two fungal proteins were found to be heritable without encoding in nucleic acid, although those properties have not been transmitted to recipient fungi as infectious elements.) Whatever its relationship to the actual infectious TSE particles, PrP clearly plays a central role in infection, because the normal prion protein must be expressed in mice if they are to acquire a TSE or to sustain replication of the infectious agents.

PrPs are glycoproteins; protease-resistant PrPs have the physical properties of amyloid proteins. The PrPs of several species of animals are very similar in their amino acid sequences and antigenicity, but are not identical in structure. The primary structure of PrP is encoded by the host and is not altered by the source of the

infectious agent provoking its formation. The function of the ubiquitous protease-sensitive **PrP precursor (designated PrP^c for "cellular" PrP or PrP-sen for protease-sensitive PrP)** in normal cells is unknown; it binds copper and may play some role in normal synaptic transmission, but it is not required for life or for relatively normal cerebral function. As noted, expression of PrP is clearly required both for development of scrapie disease and for replication of the transmissible agent in mice. The degree of homology between amino acid sequences of PrPs in different animal species may correlate with the "species barrier" that affects susceptibility of animals of one species to infection with a TSE agent adapted to grow in another species.

Attempts to find particles resembling those of viruses or virus-like agents in brain tissues of humans or animals with spongiform encephalopathies have generally been unsuccessful. Peculiar tubulovesicles have been seen in thin sections of infected brain tissue. However, it has never been established that those structures are associated with infectivity.

It has been claimed that two other human diseases—*familial Alzheimer disease* of adults and *Alpers disease* of young children—may be caused by infections with agents similar to those causing the spongiform encephalopathies. The latter is a convulsive disorder associated with hemiatrophy and status spongiosus of the cerebral gray matter. Attempts to confirm these claims have failed.

Epidemiology.

Kuru once affected many children =4 yr of age, adolescents, and young adults—mainly women—living in one area of Papua New Guinea. Transmission of the infection was interrupted more than 40 years ago, and kuru is now extremely rare and recognized only in older adults born before 1958. The complete disappearance of kuru among young people suggests that the practice of ritual cannibalism was the most important mechanism—probably the only mechanism—by which the infection spread in Papua New Guinea.

CJD, the most common human spongiform encephalopathy, was formerly thought to occur only in older adults; however, iCJD and, much more rarely, sCJD have affected adolescents and young adults. GSS and the insomnia syndromes have not been diagnosed in children or adolescents. Variant CJD has a peculiar predilection for younger people; only one patient with vCJD has been older than 55 years. CJD has been recognized worldwide, at yearly rates of 0.25–2 cases/million population (not age adjusted), with foci of considerably higher incidence among Libyan Jews in Israel, in isolated villages of Slovakia, and in other limited areas. Epidemiologic surveys have investigated several hypothetical mechanisms of spread of CJD. Person-to-person spread has been confirmed only for iatrogenic cases. The striking resemblance of CJD to scrapie prompted the suggestion that infected sheep tissues might be a source of spongiform

encephalopathy in humans. However, no reliable epidemiologic evidence suggests that exposure to potentially scrapie-contaminated animals, meat, meat products, or experimental preparations of the scrapie agent have transmitted a TSE to humans.

The same can no longer be said about BSE. The outbreak of BSE among cattle (probably infected by eating scrapie agent–contaminated meat and bone meal) was first recognized in the United Kingdom in 1986 and from there spread to native cattle in at least 21 other countries (not the United States). The finding of a new TSE in ungulate and feline animals in British zoos and then in domestic cats there raised a fear that some strain of the scrapie agent, having crossed the species barrier from sheep to cattle, had acquired a broadened range of susceptible hosts, posing a potential danger for humans. That seems to be the most plausible explanation for the occurrence of vCJD, first recognized in adolescents in 1995 and now affecting more than 130 people in the United Kingdom, six in France, and one in Italy as well as a small number of former UK residents living in Canada, Hong Kong, Ireland, and the United States. The potential of the CWD agent, now known to have infected wild deer as well as farmed deer and elk in at least five states and in Canada, to infect human beings is unknown but is currently under investigation. Preliminary epidemiologic studies have not suggested that a history of eating either venison in general or venison from animals in areas where CWD occurs is a risk factor for the later development of CJD. However, it has long seemed prudent to avoid exposing children to meat or other products likely to be contaminated with any TSE agent, including the agents of scrapie and CWD; the BSE agent clearly poses a special danger.

Iatrogenic transmission of CJD has been recognized for >25 yr (Table 253–2). Accidental transmissions of CJD have occurred by means of contaminated neurosurgical instruments or operating facilities, cortical electrodes contaminated during epilepsy surgery, injections of human cadaveric pituitary growth hormone and gonadotropin, and transplantation of contaminated corneas and allografts of human dura mater. Pharmaceuticals and tissue grafts derived from or contaminated with human neural tissues, particularly when obtained from unselected donors and large pools of donors, pose special risks. Studies of animals experimentally infected with TSE agents suggest that blood and blood components from humans in whom CJD later develops may pose a theoretical risk of transmitting disease to recipients (and such blood components are withdrawn as a precaution), but no epidemiologic study has identified any subject exposed to such products who was later diagnosed with a TSE.

Spouses and household contacts of patients are at very low risk of acquiring CJD, although two instances of conjugal CJD have been reported. However, medical personnel exposed to brains of patients with CJD may be at increased risk; at least 20 health care workers have been recognized with the disease.

Pathogenesis.

The probable portal of entry for the kuru agent has been thought to be either through the gastrointestinal tract or

TABLE 253-2 -- Iatrogenic Transmission of Creutzfeldt-Jakob Disease by Products of Human Origin

Product	No. of patients	Incubation time	
		Mean	*Range*
Cornea	3	17 mo	16–18 mo
Dura mater allograft	>100	7.4 yr	1.3–16 yr
Pituitary extract			
Growth hormone	>100*	12 yr	5–38.5 yr
Gonadotropin	4	13 yr	12–16 yr

**Twenty-nine cases /?8,000 estimated recipients in the United States (the rest in other countries).*

lesions in the mouth or integument incidentally exposed to the agent during cannibalism. Subjects with vCJD (and animals with BSE and related infections) are thought to have been similarly infected with the BSE agent through exposure to some contaminated beef product, possibly through the intestinal tract. The first site of replication of the TSE agents appears to be in tissues of the reticuloendothelial system.

The TSE agents have been detected in low titers in blood of experimentally infected animals (mice, monkeys, hamsters, and sheep), mainly, though not exclusively, associated with nucleated cells. Circulating lymphoid cells seem to be required to infect mice by peripheral routes. Limited evidence suggests that the scrapie agent also spreads to the central nervous system of mice by ascending peripheral nerves. Several researchers claim to have detected the CJD agent in human blood, although most attempts have failed.

In human kuru, it seems probable that the only portal of exit of the agent from the body, at least in quantities sufficient to infect others, was through infected tissues exposed during cannibalism. In iatrogenically transmitted CJD, the brain and eyes of patients with CJD have been the probable sources of contamination. Kidney, liver, lung, lymph node, spleen, and cerebrospinal fluid (CSF) may also contain the CJD agent. At no time during the course of any TSE have antibodies or cell-mediated immunity to the infectious agents been convincingly demonstrated in either patients or animals. However, mice must be immunologically competent to be infected with the scrapie agent by peripheral routes of inoculation.

Typical changes in TSE include vacuolation and loss of neurons with hypertrophy and proliferation of glial cells, most pronounced in the cerebral cortex in patients with CJD and in the cerebellum in those with kuru. The CNS lesions are usually most severe in or even confined to gray matter, at least early in the disease. Loss of myelin appears to be secondary to degeneration of neurons. There generally is no inflammation, but usually a marked increase in the number and size of astrocytes is noted. Status spongiosus is not a striking autopsy finding in patients with FFI, and neuronal degeneration is largely restricted to thalamic nuclei.

“Amyloid” plaques are found in the brains of all patients with GSS and in at least 70% of those with kuru; they are less common in those with CJD. Amyloid plaques are most commonly found in the cerebellum but occur elsewhere in the brain as well. In brains of patients with vCJD, plaques surrounded by halos of vacuoles (described as flower-like or “florid” plaques) have been a consistent finding. TSE plaques react with antiserum prepared against PrP, and, even in the absence of plaques, extracellular PrP can be detected in the brain parenchyma by immunostaining.

Clinical Manifestations.

Kuru is a progressive degenerative disease of the cerebellum and brainstem with less obvious involvement of the cerebral cortex. The first sign of kuru is usually cerebellar ataxia followed by progressive incoordination. Coarse, shivering tremors are characteristic. Variable abnormalities in cranial nerve function appear, frequently with impairment in conjugate gaze and swallowing. Patients die of inanition and pneumonia or of burns from cooking fires, usually 1 yr after onset. Although changes in mentation are common, there is no frank dementia or progression to coma, as in CJD. There are no signs of acute encephalitis such as fever, headaches, and convulsions.

CJD occurs throughout the world. Patients initially have either sensory disturbances (most often visual) or confusion and inappropriate behavior, with progression over weeks or months to frank dementia and ultimately coma. Some patients have cerebellar ataxia early in disease, and most experience myoclonic jerking movements. Mean survival of patients with sCJD has been <1 yr from the earliest signs of illness, although about 10% live for 2 yr. Variant CJD (Table 253–3) differs from

TABLE 253-3 -- **Clinical and Histopathologic Features of Patients with Variant and Typical Sporadic Creutzfeldt-Jakob Disease**

Feature	Variant CJD (>10 patients)	Sporadic CJD (185 patients)
Age at death (yr)* , (range)*	29 (19–74)	65
Duration of illness (mo)* , (range)*	12 (8–23)	4
Presenting signs	Abnormal behavior, dysesthesia	Dementia
Later signs	Dementia, ataxia, myoclonus	Ataxia, myoclonus
Periodic complexes on EEG	None	Most

PRNP 129 Met/Met	100%	83%
Histopathologic changes	Vacuolation, neuronal loss, astrocytosis, plaques (100%)	Vacuolation, neuronal loss, astrocytosis, plaques (?15%)
Florid PrP plaques[†]	100%	0
PrP glycosylation	BSE-like[‡]	Not BSE-like

Modified from Will RG, Ironside JW, Zeidler M, et al: A new variant of Creutzfeldt-Jakob disease in the UK. Lancet 1996;347:921–5.

BSE = bovine spongiform encephalopathy; EEG = electroencephalogram; PRNP = prion-protein-encoding gene; Met = codon 129 of one PRNP gene encoding for methionine.

*Median age and duration for vCJD; averages for typical sporadic CJD.
† Dense plaques, pale periphery, surrounded by vacuolated cells.
‡ Characterized by an excess of high-molecular-mass band and 19-kilodalton non-glycosylated band ("type 4") glycoform of PrP-res (Collinge et al., 1996).

the more common sCJD: Patients with vCJD are much younger at onset, and they more often present with complaints of dysesthesia and more subtle behavioral changes, often mistaken for psychiatric illness, than those seen in sCJD. Severe mental deterioration occurs later in the course of vCJD. Patients with vCJD have survived substantially longer than those with sCJD.

GSS is a familial disease resembling CJD but with more prominent cerebellar ataxia and amyloid plaques; dementia may appear only late in the course, and the average duration of illness is longer than that in typical sCJD. FFI and sporadic fatal insomnia are characterized by progressively severe insomnia and dysautonomia as well as ataxia, myoclonus, and other signs resembling those of CJD and GSS. Neither GSS nor an insomnia syndrome has been diagnosed in children or adolescents.

Diagnosis.

Diagnosis of spongiform encephalopathies is most often determined on clinical grounds after excluding other diseases. The presence of 14-3-3 protein in CSF may aid in distinguishing between CJD and Alzheimer disease, although this is not a consideration in children. Brain biopsy may be diagnostic of CJD, but it can be recommended only if a potentially treatable disease remains to be excluded or if there is some other compelling reason to make an antemortem diagnosis. Definitive diagnosis requires microscopic examination of brain tissue obtained at autopsy. The demonstration of protease-resistant PrP proteins in brain extracts has been useful to confirm histopathologic diagnosis. Accumulation of the abnormal PrP in lymphoid tissues, even before the onset of neurologic signs, is typical of vCJD; tonsil biopsy may replace the need for brain biopsy when antemortem diagnosis of vCJD is indicated. Transmission of disease to susceptible animals by inoculation of brain suspension must be reserved for cases of special research interest.

LABORATORY FINDINGS.

Virtually all patients with typical sporadic, iatrogenic, and familial forms of CJD have abnormal electroencephalograms (EEGs) as the disease progresses; the background becomes slow and irregular with diminished amplitude. A variety of paroxysmal discharges may also appear—slow waves, sharp waves, spike and wave complexes—and these may sometimes be unilateral or focal as well as bilaterally synchronous. Paroxysmal discharges may be precipitated by loud noise. Many patients have typical periodic suppression-burst complexes of high-voltage slow activity on EEG at some time during the illness. Patients with the vCJD had only generalized slowing, without periodic bursts of high-voltage discharges on EEG. CT or MRI may show cortical atrophy and large ventricles late in the course of CJD; many patients with vCJD have an increase in density of the pulvinar on MRI, something not typical of sCJD.

There may be modest elevation of CSF protein content in patients with TSE. Unusual protein spots were observed in CSF specimens after two-dimensional separation in gels and silver staining; the spots were identified as 14-3-3 proteins, normal proteins abundant in neurons but not ordinarily detected in CSF. (The 14-3-3 protein is not related to PrP.) However, the finding of 14-3-3 protein in CSF is not specific to CJD; it has also been detected in CSF specimens from some patients with acute viral encephalitides and recent cerebral infarctions. In clinical practice, the usual diagnostic problem is to differentiate between CJD and Alzheimer disease, and the presence of 14-3-3 proteins in CSF, while neither sensitive nor specific, militates against the latter. Finding the 14-3-3 protein in CSF has also been of some help in confirming the diagnosis of vCJD.

Treatment.

No treatment has proven to be effective. Recent studies of cell cultures and rodents experimentally infected with TSE agents suggested that treatment with chlorpromazine, quinacrine, and tetracyclines might be of benefit, especially during the incubation periods of TSEs; early reports of clinical trials based on those studies have not been encouraging, and it seems unlikely that the severe brain damage found in late disease can be reversed by such treatment. Appropriate supportive care should be provided as for other progressive fatal neurologic diseases. On the basis of experimental studies in animals, several prophylactic postexposure treatment regimens have been suggested, but none has been widely accepted.

GENETIC COUNSELING.

TSE sometimes occurs in families with a pattern of occurrence consistent with an autosomal dominant mode of inheritance. In patients with a family history of CJD, the clinical and histopathologic findings are similar to those seen in sporadic cases. In the United States, only about 10% of cases of CJD are familial. GSS and FFI are always familial. In some affected families, about 50% of siblings and children of a patient with a familial TSE eventually acquire the disease; in other families, the "penetrance" of illness may be less.

The gene coding for PrP is closely linked if not identical to that controlling the incubation periods of scrapie in sheep and both scrapie and CJD in mice. The gene encoding the PrP in humans, currently designated the *PRNF* gene, is located on the

short arm of chromosome 20. It has an open reading frame of 759 nucleotides (253 codons), in which 12 different point mutations, as well as a variety of inserted sequences encoding extra tandem-repeated octapeptides, have been linked to the occurrence of spongiform encephalopathy in families.

Although the interpretation of these findings in regard to the prion hypothesis is in dispute, in affected families with an autosomal dominant pattern of CJD or GSS, individuals who are heterozygous for linked mutations in the *PRNP* gene clearly have

a high probability of acquiring spongiform encephalopathy. The significance of mutations in the *PRNP* genes of individuals from families with no history of spongiform encephalopathy is not known. It seems wise to avoid alarming those who have miscellaneous mutations—several of which appear to represent normal polymorphisms—in the *PRNP* gene and their families because the implications are not yet clear.

The same nucleotide substitution at codon 178 of the *PRNP* gene associated with CJD in some families has been found in all patients with FFI; however, it is linked to a different amino acid-encoding sequence at codon 129, a site that is polymorphic in normal individuals. Homozygosity for methionine or for valine at codon 129, especially for methionine, seems to increase susceptibility to iCJD and sCJD, although methionine-valine heterozygotes are also susceptible to both diseases. So far, all patients with vCJD to be genotyped have been homozygous for methionine at codon 129 of the PRNP gene.

Prognosis.

The prognosis of spongiform encephalopathies is uniformly poor. About 10% of patients may survive for =1 yr, but the quality of life is poor.

Prevention.

Standard precautions should be used for handling all human tissues, blood, and body fluids. Materials and surfaces known to be contaminated with tissues or fluids from patients suspected of having CJD must be treated with great care. Whenever possible, contaminated instruments should be discarded by careful packaging and incineration. Contaminated tissues and biologic products probably cannot be completely freed of infectivity without destroying their structural integrity and biologic activity; therefore, the medical and family histories of individual tissue donors should be carefully reviewed to exclude a diagnosis of TSE. Histopathologic examination of brain tissues of donors and testing for abnormal PrP should be performed where feasible. Although no method of sterilization can be relied on to remove all infectivity from contaminated surfaces, exposure to moist heat, sodium hydroxide, chlorine bleach, concentrated formic acid, and guanidine salts markedly reduces infectivity.

Chapter 254 - Acquired Immunodeficiency Syndrome (Human Immunodeficiency Virus)

Ram Yogev
Ellen Gould Chadwick

Recent advances in research and major improvements in the treatment and management of HIV infection have brought about a substantial decrease in the incidence of new infections and AIDS in children born in the United States and Western Europe. However, most HIV-infected children are born in developing countries. It is estimated that in 2001, 800,000 children <15 yr of age were newly infected with HIV and that 2.7 million children were living with HIV or AIDS. In addition, because HIV-infected mothers are likely to die of AIDS, 10 million children have been orphaned thus far and an estimated 20 million will be orphaned by 2010. HIV infection in children progresses more rapidly than in adults, and some untreated children die within the first 2 yr of life. In general, this rapid progression is correlated with higher viral burden and faster depletion of infected CD4 lymphocytes in infants and children than in adults. Newer diagnostic tests and the availability of potent drugs to inhibit HIV replication have dramatically increased our ability to prevent and control this devastating disease.

Etiology.

HIV-1 and HIV-2 are members of the Retroviridae family and belong to the *Lentivirus* genus, which includes cytopathic viruses causing diverse diseases in several animal species. Each virus particle contains two copies of the genome. The HIV-1 genome is single-stranded RNA that is 9.2?kb in size. At both ends of the genome there are identical regions, called **long terminal repeats,** which contain the regulation and expression genes of HIV. The remainder of the genome includes three major sections: the **GAG** region, which encodes the viral core proteins (e.g., p24, p17, p9, p6, which are derived from the precursor p55), the **POL** region, which encodes the viral enzymes (i.e., reverse transcriptase [p51], protease [pl0], and integrase [p32]); and the **ENV** region, which encodes the viral envelope proteins (i.e., gp120 and gp41, which are derived from the precursor gp160). Other regulatory proteins such as tat (pl4), rev (p19), nef (p27), vpr (pl5), and vif (p23) are involved in transactivation, viral mRNA expression, viral replication, induction of cell-cycle arrest, promotion of nuclear import of viral reverse transcription complexes, downregulation of cell surface receptors CD4 and class I major histocompatibility complex, proviral

DNA synthesis, and virus release (Fig. 254–1).

The major external viral protein of HIV-1 is a heavily glycosylated gp120 protein that is associated with the transmembrane glycoprotein gp41; gp41 is very immunogenic and is used to detect HIV-1 antibodies in diagnostic assays; gp120 is a complex

Figure 254-1 The HIV virus and associated proteins and their functions.

molecule that includes the highly variable **V3 loop**. This region is immunodominant for neutralizing antibodies. The heterogeneity of gp120 presents major obstacles in establishing an effective HIV vaccine. The gp120 also carries the binding site for the CD4 molecule, the most common host cell surface receptor of T lymphocytes. Several chemokines serve as co-receptors for the envelop glycoproteins permitting membrane fusion and entry into the cell. Most HIV strains have a specific tropism for one of the chemokines: the fusion-inducing molecule, CXCR-4, which has been shown to act as a co-receptor for HIV attachment to lymphocytes, and CCR-5, a ß chemokine receptor that facilitates HIV entry into macrophages. Several other chemokine receptors (e.g., CCR-3) have been shown in vitro to also serve as co-receptors.

Other mechanisms of attachment of HIV to cells use non-neutralizing antiviral antibodies and complement receptors. The Fab portion of these antibodies attaches to the virus surface, and the Fc portion binds to cells that express Fc receptors (i.e., macrophages, fibroblasts), thus facilitating virus transfer into the cell. Other cell surface receptors such as mannose-binding protein on macrophages and DC-specific C-type lectin (DC-SIGN) on dendritic cells also bind to the HIV-1 envelope glycoprotein and increase the efficiency of the virus infectivity. Following viral attachment, gp120 and the CD4 molecule undergo conformational changes, and gp41 interacts with the fusion receptor on the cell surface. Viral fusion with the cell membrane allows entry of viral RNA into the cell cytoplasm. Viral DNA copies are then transcribed from the virion RNA through viral reverse transcriptase enzyme activity, and duplication of the DNA copies produces double-stranded circular DNA. The HIV-1 reverse transcriptase is error-prone and lacks error-correcting mechanisms. Thus, many mutations arise, creating wide genetic variation in HIV-1 isolates even within an individual patient. The circular DNA is transported into the cell nucleus where it is integrated into chromosomal DNA and referred to as the provirus. The provirus can remain dormant for extended periods. Depending on the relative expression of the viral regulatory genes (e.g., tat, rev, nef), the proviral DNA may encode production of the viral RNA genome, which in turn leads to production of viral proteins necessary for viral assembly.

HIV-1 transcription is followed by translation. A capsid polyprotein is cleaved to produce, among others, the virus-specific protease (p10). This enzyme is critical for HIV-1 assembly. Several HIV-1 antiprotease drugs have been developed, targeting the increased sensitivity of the viral protease, which differs from the cellular proteases. The RNA genome is then incorporated into the newly formed viral capsid. As the new virus is formed, it buds through the cell membrane and is released.

The HIV diversity (e.g., groups M [main], O [outlier], N [non M, non O]) probably occurred from multiple zoonotic infections from primates in different geographic regions. Group M diversified to several subtypes (or clades A to H). In each region of the world certain clades predominate. For example, clade B is found in South America, clade E in Thailand, and clade C in South Africa. Clades are mixed in some patients due to HIV recombination, and some crossing between groups (i.e., M and O) has been reported.

HIV-2 is a rare cause of infection in children. It is most prevalent in Western and Southern Africa. The diagnosis of HIV-2 infection is more difficult because the standard antibody assays are HIV-1–specific and may give indeterminate results in those with HIV-2 infection. If HIV-2 is suspected, a specific test that detects antibody to HIV-2 peptides should be used.

Epidemiology.

The World Health Organization (WHO) estimated that more than 40 million persons worldwide were living with HIV infection at the end of 2001; 2.7 million of these were children <15 yr of age. In 2001 alone, 5 million people acquired HIV and 3 million died, including 580,000 children. More than 90% of HIV-infected individuals live in developing nations where an estimated 720,000 infants were infected through perinatal transmission in 2001. Sub-Saharan Africa accounts for the fastest growing epidemic, with almost 90% of the world's total population of HIV-infected children. India and Thailand dominate the epidemic in Southeast Asia, with more recent expansion into Vietnam, China, and Cambodia.

Worldwide, 60% of HIV-infected individuals are women, and heterosexual transmission accounts for most HIV spread. In the United States, women account for 26% of AIDS cases reported to the CDC in 2000. In 2000, the percentage of American women whose exposure category was heterosexual contact (38%) surpassed that of injecting drug use (IDU) (25%). However, heterosexual transmission is probably even more common because further investigation of the category “risk not reported or identified” (36%) often leads to reclassification as heterosexual transmission. These are women who have been infected heterosexually by men unrecognized to be infected or to be in a high-risk group. Among mothers giving birth to children with AIDS, heterosexually acquired infection and “risk not reported” are the most common exposure categories, accounting for approximately 80% of the total. The estimated number of U.S. children with AIDS diagnosed each year increased from 1984 to 1992, then declined by 75% by 2000. This decline most likely reflects the effectiveness of zidovudine (ZDV) and other antiretroviral drugs in reducing perinatal HIV transmission. However, while the number of HIV-infected infants is decreasing in industrialized nations, the worldwide number of HIV-infected children is increasing dramatically because of lack of funds to provide medications to prevent perinatal transmissions.

In the United States, virtually all HIV infections in children <13 yr of age are the result of vertical transmission from an HIV-infected mother. A vanishing minority of children were infected through receipt of contaminated blood products and/or clotting factors (2%), primarily before 1985 when screening of the blood supply was instituted. Children of racial and ethnic minority groups are disproportionally over-represented,

in particular non-Hispanic African-Americans and Hispanics. Race/ethnicity is not a risk factor for HIV infection per se but more likely reflects other factors that may be predictive of increased risk for HIV infection, such as lack of educational and economic opportunities and higher rates of IDU. The Northeast (44%) and the South (36%) account for most U.S. pediatric cases; 85% were diagnosed in metropolitan areas with populations >500,000 persons and 9% in metropolitan areas with populations of 50,000–500,000 persons.

Although adolescents (13–19 yr of age) with AIDS represent only 0.5% of U.S. cases, they constitute one of the fastest growing groups of newly infected persons in the country. Considering the long latency period between the time of infection and the development of clinical symptoms, reliance on AIDS case definition

surveillance data severely under-represents the impact of the disease in adolescents. Based on a median incubation period of 8–12 yr, it has been estimated that 15–20% of all AIDS cases were acquired between 13–19 yr of age. Risk factors for HIV infection vary by gender in adolescents. Whereas 36% of the cumulative number of teenaged males with AIDS were infected by contaminated blood or blood products (primarily patients with hemophilia), only 7% of females were infected via this route. As in the adult population, the majority of teenaged males with AIDS who acquired HIV through sexual contact had male-to-male transmission. In contrast, more than half of adolescent females with AIDS were infected through heterosexual contact and one-sixth through IVDU, compared with 5% and 6%, respectively, in teenaged males.

As in the pediatric population, adolescent racial and ethnic minority populations are over-represented, especially among females. In addition, a greater proportion of female adolescents have AIDS (male:female ratio 1.2:1) than do female adults >25 yr of age (male:female ratio 4.5:1).

TRANSMISSION.

Transmission of HIV-1 occurs via sexual contact, parenteral exposure to blood, or vertical transmission from mother to child. The primary route of infection in the pediatric population is vertical transmission, accounting for virtually all new cases. Rates of transmission of HIV from mother to child have varied in different parts of the United States and among countries. Most large studies in the United States and Europe have documented transmission rates in untreated women between 12–30%. In contrast, transmission rates in Africa and Haiti are higher (25–52%). Perinatal treatment of HIV-infected mothers with antiretroviral drugs has dramatically decreased these rates.

Vertical transmission of HIV can occur before (intrauterine), during (intrapartum), or after (through breast-feeding) delivery. Intrauterine transmission has been suggested by identification of HIV by culture or polymerase chain reaction (PCR) in fetal tissue as early as 10 weeks' gestation. In addition, first-trimester placental tissue from HIV-infected women has been demonstrated to contain HIV by in situ hybridization and immunocytochemistry. It is generally accepted that 30% to 40% of infected newborns are infected in utero, because this percentage of infants has laboratory evidence of infection (positive viral culture or PCR) within the 1st wk of life. Some studies have found that viral detection soon after birth also correlates with early onset of symptoms and rapid progression to AIDS, consistent with more long-standing infection during gestation.

The highest percentage of HIV-infected children acquire the virus intrapartum, evidenced by the fact that 60–70% of infected infants do not demonstrate detectable virus before 1 wk of age. The mechanism of transmission appears to be exposure to infected blood and cervicovaginal secretions in the birth canal, where HIV is found in high titers during late gestation and delivery. Furthermore, the international registry of HIV-exposed twins found that first-born twins were three times more likely to be infected, reflecting the longer time that twin A is exposed to the birth canal.

The least common route of vertical transmission in industrialized nations is breast-feeding; however, this is an important transmission route in developing countries. Both free and cell-associated virus have been detected in breast milk from HIV-infected mothers. A meta-analysis of prospective studies found that the additional risk of transmission through breast-feeding in women with HIV infection before pregnancy was 14% compared with a 29% increase in breast-feeding women who acquired HIV postnatally. This suggests that the viremia experienced by the mother during primary infection doubles the risk of transmission. It therefore seems reasonable for women to substitute infant formula for breast milk if they are known to be HIV-infected or are at risk for ongoing sexual or parenteral exposure to HIV. However, the WHO recommends that in developing countries where other diseases (e.g., diarrhea, pneumonia, and malnutrition) substantially contribute to a high infant mortality rate, the benefit of breast-feeding outweighs the risk of HIV transmission, and HIV-infected women should breast-feed their infants.

Several risk factors influence the rate of vertical transmission: preterm delivery (<34 wk gestation), a low maternal antenatal CD4 count, and use of illicit drugs during pregnancy. The most important variables appear to be >4?hr duration of ruptured membranes and birthweight <2500?g, each of which doubles the transmission rate. A meta-analysis of more than 1,000 pregnancies demonstrated that elective cesarean delivery decreased transmission by 87% if used in conjunction with zidovudine therapy in the mother and infant. However, because these data predated the advent of **highly active antiretroviral therapy (HAART)**, the additional benefit of cesarean section is probably negligible if the mother's viral load is <500 copies/mL. Although several studies have shown an increased rate of transmission in women with advanced disease (i.e., AIDS) or high viral load (>50,000 copies/mL), some transmitting mothers in each group were asymptomatic or had a low, but detectable, viral load.

Transfusions of infected blood or blood products have accounted for 3–6% of all pediatric AIDS cases. The period of highest risk was between 1978 and 1985, before the availability of HIV antibody–screened blood products. Whereas the prevalence of HIV infection in individuals with hemophilia treated before 1985 was as high as 70%, heat treatment of factor VIII concentrate and HIV antibody screening of donors has virtually eliminated HIV transmission in this population. Blood donor screening has dramatically reduced, but not eliminated, the risk of transfusion-associated HIV infection. The rate of HIV transmission through antibody-screened blood in the United States is estimated to be approximately 1/60,000 transfused units. In many

developing countries, screening of blood donors is not uniform, and the risk of transmitting HIV infection via transfusion is still substantial.

Although HIV can be isolated rarely from saliva, it is in very low titers (<1 infectious particle/mL) and has not been implicated as a transmission vehicle. Studies of hundreds of household contacts of HIV-infected individuals have found that the risk of HIV transmission is practically nonexistent. Only a few cases have been reported in which urine or feces (possibly devoid of visible blood) have been proposed as a possible vehicle of HIV transmission.

In the pediatric population, sexual transmission is infrequent, but a small number of cases resulting from sexual abuse have been reported. In contrast, sexual contact is a major route of transmission in the adolescent population, accounting for most of the cases.

Pathogenesis.

When the mucosa serves as the portal of entry for the HIV, the first cells to be infected are the dendritic cells. These cells are in charge of collecting and processing antigens introduced from the periphery and transporting them to the lymphoid tissue. The HIV does not infect the dendritic cell but it binds to its DC-SIGN surface molecule, which allows the virus to survive until it reaches the lymphatic tissue. In the lymph node, the HIV selectively binds to cells expressing CD4 molecules on their surface, primarily helper T lymphocytes (CD4 cells) and cells of the monocyte-macrophage lineage. Other cells bearing CD4, such as microglia, astrocytes, oligodendroglia, and placental tissue containing villous Hofbauer cells, may also be infected by HIV. Usually, CD4 lymphocytes, recruited to respond to viral antigen, migrate to the lymph nodes where they become activated and proliferate, making them highly susceptible to HIV infection. This antigen-driven migration and accumulation of CD4 cells within the lymphoid tissue may contribute to the generalized lymphadenopathy characteristic of the acute retroviral syndrome in adults and adolescents. Recently it was shown that

the HIV preferentially infects the very cells that respond to it (i.e., HIV-specific memory CD4 cells), which accounts for the progressive loss of these cells' response and the subsequent loss of control of HIV replication. When the HIV replication reaches a threshold (usually within 3–6 wk from the time of infection), a burst of plasma viremia occurs. This intense viremia cause flulike symptoms (i.e., fever, rash, lymphadenopathy, and arthralgia) in 50–70% of infected adults. With establishment of a cellular and humoral immune response within 2–4 mo, the viral load in the blood declines substantially, and patients enter a phase characterized by a lack of symptoms and a return of CD4 cells to only moderately decreased levels.

Early HIV-1 replication in children has no apparent clinical manifestations. Whether tested by virus isolation or by PCR for viral nucleic acid sequences, fewer than 50% of HIV-1–infected infants demonstrate evidence of the virus at birth. The virus load increases by 1–4 mo, and almost all HIV-infected infants have detectable HIV-1 in peripheral blood by 4 mo of age.

In adults, the long period of clinical latency (up to 8–12 yr) is not indicative of viral latency. In fact, there is a very high turnover of virus and CD4 lymphocytes (more than a billion cells per day), which gradually causes deterioration of the immune system, evidenced particularly by depletion of CD4 cells. These cells may be destroyed by multiple mechanisms: HIV-mediated single cell killing, formation of multinucleated giant cells of infected and uninfected CD4 cells (**syncytia formation**), virus-specific immune responses, superantigen-mediated activation of T cells (rendering them more susceptible to infection with HIV), and programmed cell death (apoptosis). The viral burden in the lymphoid organs is greater than that in the peripheral blood during the asymptomatic period. As HIV virions and their immune complexes migrate through the lymph nodes, they are trapped in the network of dendritic follicular cells. Because the ability of HIV to replicate in T cells depends on the state of activation of the cells, the immune activation that takes place within the microenvironment of the nodes in HIV disease serves to promote infection of new CD4 cells as well as subsequent viral replication within the cells. Viral replication in monocytes, which can be infected productively yet resist killing, explains their role as reservoirs of HIV and as effectors of tissue damage in organs such as the brain.

Cell-mediated and humoral responses occur early in the infection. The CD8 T cells play an important role in containing the infection. HIV-specific cytotoxic T lymphocytes (CTLs) develop against both the structural (i.e., ENV, POL, GAG) and regulatory (e.g., tat) viral proteins. The CTL cells appear at the end of the acute retroviral infection as the viral replication is controlled. The CTL cells control the infection by killing HIV-infected cells before new viruses are produced and by secreting potent antiviral factors that compete with the virus for its receptors (e.g., CCR5). Neutralizing antibodies appear later during the infection and seem to help in the continued suppression of viral replication during clinical latency. There are at least two possible mechanisms that control the steady-state viral load level during the chronic clinical latency. One mechanism may be the limited availability of activated CD4 cells which prevent further increase in viral load due to a set point (i.e., controlled) replication. The other mechanism, the immune-control, suggests that the development of active immune response (whose magnitude is controlled by the amount of the viral antigen) limits the viral replication at a steady state. There is no general consensus about which of these two mechanisms is more important. The CD4–cell limitation mechanism accounts for the effect of antiretroviral therapy, whereas the immune-control mechanism emphasizes the importance of immune-modulation treatment (e.g., cytokines, vaccines) to increase the efficiency of the immune response, which, in turn, slows the disease progression.

A group of cytokines, such as tumor necrosis factor a (TNFa), TNFß, interleukin 1 (IL-1), IL-3, IL-6, interferon-?, granulocyte-macrophage colony-stimulating factor (GM-CSF), and macrophage colony-stimulating factor, play an integral role in upregulating HIV expression from a state of quiescent infection to active viral replication. Other cytokines such as interferon ? (INF?), INF-ß, and transforming growth factor D exert a suppressive effect on HIV replication. The interactions among these cytokines influence the concentration of viral particles in the tissues. Plasma concentrations of cytokines need not be elevated for them to exert their effect, because they are produced and act locally in the tissues. Thus, even during states of apparent immunologic quiescence, the complex interaction of cytokines

sustains a constant level of viral expression, particularly in the lymph nodes.

Commonly the phenotypic HIV isolated during the clinical latency period grows slowly in culture and produces low titers of reverse transcriptase. These isolates are called **non–syncytium-inducing (NSI) viruses**, which use CCR5 as their co-receptor. By the late stages of the clinical latency, the isolated virus is phenotypically different. It grows rapidly and to high titers in culture and it uses CXCR4 as its co-receptor. These isolates are called **syncytium-inducing (SI) viruses**. The switch from NSI to SI increases the capacity of the virus to replicate, to infect a broader range of target cells (CXCR4 is more widely expressed on resting and activated immune cells), and to kill T cells more rapidly and efficiently. As a result, the clinical latency phase is over and progression toward AIDS is noted. The progression of disease is related temporally to the gradual disruption of lymph node architecture and degeneration of the follicular dendritic cell network with loss of its ability to trap HIV particles. This frees the virus to recirculate, producing high levels of viremia and an increased disappearance of CD4 T cells during the later stages of disease.

Before HAART was available, three distinct patterns of disease were described in children. Approximately 15–25% of HIV-infected newborns in developed countries present with a rapid disease course, with onset of AIDS and symptoms during the first few months of life and, if untreated, a median survival time of 6–9 mo. In resource-poor countries, >85% of the HIV-infected newborns will have such rapidly progressing disease. It has been suggested that if intrauterine infection coincides with the period of rapid expansion of CD4 cells in the fetus, it could effectively infect the majority of the body's immunocompetent cells. The normal migration of these cells to the marrow, spleen, and thymus would result in efficient systemic delivery of HIV, unchecked by the immature immune system of the fetus. Thus infection would be established before the normal ontogenic development of the immune system, causing more severe impairment of immunity. Most children in this group have a positive HIV-1 culture and/or detectable virus in the plasma (median level 11,000 copies/mL) in the first 48?hr of life. This early evidence of viral presence suggests that the newborn was infected in utero. The viral load rapidly increases and peaks by 2–3 mo of age (median 750,000 copies/mL) and subsequently declines slowly. In contrast to the viral load in adults, the viral load in infants stays high for at least the first 2 yr of life.

The majority of perinatally infected newborns (60–80%) present with a second pattern, that of a much slower progression of disease with a median survival time of 6 yr. Many patients in this group have a negative viral culture or PCR in the 1st wk of life and are therefore considered to be infected intrapartum. In a typical patient, the viral load rapidly increases by 2–3 mo of age (median 100,000 copies/mL) and slowly declines over a period of 24 mo. The slow decline in viral load is in sharp contrast to the rapid decline after primary infection seen in adults. This observation can be explained only partially by the immaturity of the immune system in newborns and infants.

The third pattern of disease (i.e., long-term survivors) occurs in a small percentage (<5%) of perinatally infected children who have minimal or no progression of disease with relatively normal CD4 counts and very low viral loads for longer than 8 yr.

HIV-infected children have changes in the immune system that are similar to those in HIV-infected adults. CD4 cell depletion may be less dramatic because infants normally have a relative lymphocytosis. Therefore, for example, a value of 1,500 CD4 cells/mm^3 in children <1 yr of age is indicative of severe CD4 depletion and is comparable to <200 CD4 cells/mm^3 in adults. Lymphopenia is relatively rare in perinatally infected children and is usually only seen in older children or those with end-stage disease. Although cutaneous anergy is common during HIV infection, it is also frequent in healthy children <1 yr of age and thus its interpretation is difficult in infected infants.

B-cell activation occurs in most children early in the infection as evidenced by hypergammaglobulinemia (>1.750?g/L) with high levels of anti–HIV-1 antibody. This response may reflect both dysregulation of T-cell suppression of B-cell antibody synthesis and active CD4 enhancement of B-lymphocyte humoral response. In some children, evidence of specific antibody production does not occur and in others adequate antibody levels do not confer protection. Because hypergammaglobulinemia is so common in HIV-infected children, it may serve as a surrogate marker of HIV infection in symptomatic children in whom specific diagnostic tests (e.g., PCR, culture) are not available or are too expensive. Hypogammaglobulinemia is very rare (<1%). Central nervous system (CNS) involvement is more common in pediatric patients than in adults. Macrophages and microglia play an important role in HIV neuropathogenesis, and data suggest that astrocytes may also be involved. Although the specific mechanisms for encephalopathy in children are not yet clear, the developing brain in young infants, with its delayed myelinization, is more vulnerable to invasion by HIV.

Understanding the complex relationship between the virus-specific immune responses and the mechanisms used by the virus to survive are crucial for therapeutic strategies. Even though viral replication currently can be suppressed by antiretroviral drugs, it is important to develop strategies to modulate the immune response.

Clinical Manifestations.

The clinical manifestations of HIV infection vary widely among infants, children, and adolescents. In most infants, physical examination at birth is normal. Initial symptoms may be subtle, such as lymphadenopathy and hepatosplenomegaly, or nonspecific, such as failure to thrive, chronic or recurrent diarrhea, interstitial pneumonia, or oral thrush, and may be distinguishable only by their persistence. Whereas systemic and pulmonary findings are common in the United States and Europe, chronic diarrhea, wasting, and severe malnutrition predominate in Africa. Symptoms found more commonly in children than adults with HIV infection include recurrent bacterial infections, chronic parotid swelling, lymphocytic interstitial pneumonitis (LIP), and early onset of progressive neurologic deterioration.

The HIV classification system is used to categorize the stage of pediatric disease by using two parameters: clinical status, and degree of immunologic impairment (Table

254–1). Among the clinical categories, category A (mild symptoms) includes children

TABLE 254-1 -- CDC Pediatric HIV Classification*

Immune Categories	Clinical Categories			
	N—No Signs/Symptoms	***A—Mild Signs/Symptoms***	***B—Moderate Signs/Symptoms†***	***C—Severe Signs/Symptoms†***
1. No evidence of suppression	N1	A1	B1	C1
2. Evidence of moderate suppression	N2	A2	B2	C2
3. Severe suppression	N3	A3	B3	C3

From Centers for Disease Control and Prevention: 1994 revised classification system for human immunodeficiency virus infection in children less than 13 years of age. MMWR 1994;43 (RR-12):1–10.

** Children whose HIV infection status is not confirmed are classified by using the above grid with a letter E (for perinatally exposed) placed before the appropriate classification code (e.g., EN2).*
†Category C and lymphoid interstitial pneumonitis (LIP) in category B are reportable to state and local health departments as AIDS.

with at least two mild symptoms such as lymphadenopathy, parotitis, hepatomegaly, splenomegaly, dermatitis, and recurrent or persistent sinusitis or otitis media. Category B (moderate symptoms) includes, for example, children with LIP, oropharyngeal thrush persisting for >2 mo, recurrent or chronic diarrhea, persistent fever >1 mo, hepatitis, recurrent herpes simplex stomatitis or HSV esophagitis or pneumonitis, disseminated varicella (i.e., with visceral involvement), cardiomegaly, or nephropathy. Category C (severe symptoms) includes, for example, children with two serious bacterial infections (e.g., sepsis, meningitis, pneumonia) in a 2-yr period, esophageal or lower respiratory tract candidiasis, cryptococcosis, cryptosporidiosis (>1 mo), encephalopathy, malignancies, disseminated mycobacterial infection, *Pneumocystis carinii* pneumonia (PCP), cerebral toxoplasmosis (onset after 1 mo of age) and severe weight loss.

The immune classification is based on the absolute CD4 lymphocyte count or the percentage of CD4 cells (CD4%) (Table 254–2). Age adjustment of the absolute CD4 count is necessary because counts that are relatively high in normal infants decline steadily until 6 yr of age, when they reach adult norms. If there is a discrepancy between the CD4 count and percentage, the disease is classified into the more severe category.

INFECTIONS.

Approximately 20% of AIDS-defining illnesses in children are recurrent bacterial infections caused primarily by encapsulated organisms such as *Streptococcus pneumoniae* and *Salmonella*. Other pathogens including *Staphylococcus, Enterococcus, Pseudomonas aeruginosa, Haemophilus influenzae*, and other gram-positive and gram-negative organisms may also be seen. Most of these infections are the result of HIV-related disturbances in humoral immunity. The most common serious infections are bacteremia, sepsis, and pneumonia, accounting for more than 50% of infections in HIV-infected children. Meningitis, urinary tract infections, deep-seated abscesses, and bone/joint infection occur less frequently. Milder recurrent infections, such as otitis media, sinusitis, and skin and soft tissue infections are very common and may be chronic with atypical presentations.

Opportunistic infections are generally seen in children with severe depression of the CD4 count. In adults, these infections usually represent reactivation of a latent infection acquired early in life. In contrast, young children generally have primary infection and, lacking prior immunity, often have a more fulminant course of disease. This principle is best illustrated by PCP, the most common opportunistic infection in the pediatric population. The peak incidence of PCP occurs at age 3–6 mo with the highest mortality rate in children <1 yr of age. However, newer, more aggressive approaches to treatment have improved the outcome substantially.

The classic clinical presentation of PCP includes acute onset of fever, tachypnea, dyspnea, and marked hypoxemia; however, in some children more indolent development of hypoxemia may precede other clinical or roentgenographic manifestations. Chest radiography findings most commonly consist of interstitial infiltrates or diffuse alveolar disease, which rapidly progresses. Nodular lesions, streaky or lobar infiltrates, or pleural effusions

TABLE 254-2 -- CDC Revised Pediatric HIV Classification: Immune Categories Based on CD4 Count or CD4 Percentage

Immune Categories	<12 Months		1–5 Years		=6 Years	
	Cells/µL	***%***	***Cells/µL***	***%***	***Cells/µL***	***%***
1. No evidence of suppression	=1500	=25	=1000	=25	=500	=25
2. Evidence of moderate suppression	750–1499	15–24	500–999	15–24	200–499	15–24
3. Severe suppression	<750	<15	<500	<15	<200	<15

may occasionally be seen. Diagnosis is established by demonstration of *P. carinii* with appropriate staining of bronchoalveolar fluid lavage; rarely, an open lung biopsy is necessary.

The first-line therapy for PCP is intravenous trimethoprim (TMP)-sulfamethoxazole (SMZ) (15–20?mg/kg/24?hr of TMP and 75–100?mg/kg/24?hr of SMZ q 6?hr IV) with adjunctive corticosteroids. When the patient has improved, therapy with oral TMP-SMZ should be continued for a total of 21 days. Historically, up to one third of

HIV-infected children have had allergic reactions to TMP-SMZ that have required desensitization. However, because of the use of adjunctive corticosteroid therapy, this is considerably less frequent. Alternative therapy for PCP includes intravenous administration of pentamidine (4?mg/kg/24?hr). Other regimens such as TMP plus dapsone, clindamycin plus primaquine, or atovaquone are used as alternatives in adults but have not been widely used in children to date.

Atypical mycobacterial infection, particularly with *Mycobacterium avium-intracellulare* complex (MAC), may cause disseminated disease in HIV-infected children who are severely immunosuppressed. The incidence of MAC infection in children with <100 CD4 cells/mm^3 who were not treated with antiretroviral drugs was estimated to be 10%. Effective antiretroviral combination therapies that result in viral suppression have made MAC infections rare. Disseminated MAC infection is characterized by fever, malaise, weight loss and night sweats; diarrhea, abdominal pain, and rarely intestinal perforation or jaundice (due to biliary tract obstruction by lymphadenopathy) may also be present. Diagnosis is made by isolation of MAC from blood, bone marrow, or tissue; the isolated presence of MAC in the stool does not confirm a diagnosis of disseminated MAC. Treatment can reduce symptoms and prolong life but is only capable of suppressing the infection as long as severe CD4 depletion persists. Therapy should include at least two drugs: clarithromycin (or azithromycin) and ethambutol. A third drug (e.g., rifabutin, rifampin, ciprofloxacin, or amikacin) is generally added to decrease the emergence of drug-resistant isolates. Careful consideration of possible drug-drug interactions with antiretroviral agents is necessary before initiation of disseminated MAC therapy. Drug susceptibilities should be ascertained and the treatment regimen adjusted accordingly in the event of inadequate clinical response to therapy. Because of the great potential for toxicity with most of these medications, surveillance for side effects should be ongoing.

Oral candidiasis is the most common fungal infection seen in HIV-infected children. Oral nystatin suspension (2–5?mL qid) is often effective. Clotrimazole troches are an effective alternative. In refractory cases, oral amphotericin suspension should be considered. Oral thrush progresses to involve the esophagus in as many as 20% of children, presenting with symptoms such as anorexia, dysphagia, vomiting, and fever. Treatment with oral fluconazole (4–6?mg/kg/24?hr) for 14 days generally results in rapid improvement in symptoms. Disseminated histoplasmosis and coccidiomycosis or cryptococcosis are rare in pediatric patients but may occur in endemic areas. Parasitic infections such as intestinal cryptosporidiosis and microsporidiosis and rarely isosporiasis or giardiasis are other opportunistic infections that cause significant morbidity. Although usually self-limiting diseases in healthy hosts, they cause severe chronic diarrhea often leading to malnutrition in HIV-infected children with low CD4 counts. Until recently, there was no effective therapy for cryptosporidiosis, which generally resulted in lifelong infection. However, preliminary data on an investigational agent, nitazoxanide, has been promising, with clearance of the infection in some patients. Albendazole was reported to be effective in a few cases of chronic microsporidiosis, and TMP-SMZ seems to be effective for isosporiasis.

Viral infections, especially with the herpesvirus group, pose significant problems for HIV-infected children. Herpes simplex virus causes recurrent gingivostomatitis, which may be complicated by local and distant cutaneous dissemination. Primary varicella-zoster virus (VZV) infection (chickenpox) may be prolonged and complicated by bacterial infections or visceral dissemination, including pneumonitis.

Recurrent, atypical, or chronic episodes of herpes zoster are often debilitating and require prolonged therapy with acyclovir; in rare instances, VZV has developed resistance to acyclovir, requiring the use of foscarnet. Disseminated cytomegalovirus (CMV) infection can occur with severe CD4 depletion (<50 CD4 cells/mm^3) and may involve single or multiple organs. Retinitis, pneumonitis, esophagitis, gastritis with pyloric obstruction, hepatitis, colitis, and encephalitis have been reported, but these complications are rarely seen if HAART is given. Ganciclovir (5?mg/kg bid IV) or foscarnet (60?mg/kg tid IV) are the drugs of choice. Measles may occur despite immunization and may present without the typical rash. It often disseminates to the lung or brain with a high mortality rate. Respiratory viruses such as respiratory syncytial virus (RSV) and adenovirus may present with prolonged symptoms and persistent viral shedding.

CENTRAL NERVOUS SYSTEM.

The incidence of central nervous system (CNS) involvement in perinatally infected children is 50–90% in developing countries but lower in developed countries, with a median onset at 19 mo of age. The most common presentation is progressive encephalopathy with loss or plateau of developmental milestones, cognitive deterioration, impaired brain growth resulting in acquired microcephaly, and symmetric motor dysfunction. Encephalopathy may be the initial manifestation of the disease or may present much later when severe immune suppression occurs. With progression, marked apathy, spasticity, hyperreflexia, and gait disturbance may occur, as well as loss of language, oral, fine, and/or gross motor skills. The encephalopathy may progress intermittently, with periods of deterioration followed by transiently stable plateaus. Older children may exhibit behavioral problems and learning disabilities. Associated abnormalities identified by neuroimaging techniques include cerebral atrophy in up to 85% of children with neurologic symptoms, increased ventricular size, basal ganglia calcifications, and, less frequently, leukomalacia.

Focal neurologic signs and seizures are unusual and may imply a comorbid pathologic process such as a CNS tumor, opportunistic infection, or stroke. CNS lymphoma may present with a new onset of focal neurologic findings, headache, seizures, and mental status changes. Characteristic findings on neuroimaging studies include a hyperdense or isodense mass with variable contrast enhancement or a diffusely infiltrating contrast-enhancing mass. CNS toxoplasmosis is exceedingly rare in young infants, but may occur in HIV-infected adolescents;

the overwhelming majority of these cases have presence of serum IgG antitoxoplasma as a marker of infection. Other opportunistic infections of the CNS are rare and include CMV, JC virus (causing progressive multifocal leukoencephalopathy), herpes simplex virus, and cryptococcal or coccidioides meningitis. Although the true incidence of cerebrovascular disorders (both hemorrhagic and nonhemorrhagic strokes) is unclear, 6–10% of children from large clinical series have been affected.

RESPIRATORY TRACT.

Recurrent upper respiratory tract infections such as otitis media and sinusitis are very common. Although the typical pathogens (e.g., *S. pneumoniae, H. influenzae, Moraxella catarrhalis*) are most common, unusual pathogens, such as *P. aeruginosa*, yeast and anaerobes, may be present in chronic infections and result in complications such as invasive sinusitis and mastoiditis.

LIP is the most common chronic lower respiratory tract abnormality, occurring in approximately 25% of HIV-infected children. LIP is a chronic process with nodular lymphoid hyperplasia in the bronchial and bronchiolar epithelium, often leading to progressive alveolar capillary block over months to years. It has a characteristic chronic diffuse reticulonodular pattern on chest radiograph (rarely with hilar lymphadenopathy), which allows a presumptive diagnosis to be made radiographically before the onset of symptoms. Clinically, there is an insidious onset of tachypnea, cough, and mild to moderate hypoxemia with normal auscultatory findings or minimal rales. Progressive disease may be accompanied by digital clubbing and symptomatic hypoxemia, which usually resolves with oral corticosteroid therapy. The etiology of LIP has not been proven, although several studies suggest LIP is associated with a primary Epstein-Barr virus infection in the setting of HIV infection.

Most symptomatic HIV-infected children experience at least one episode of pneumonia during the course of their disease. *S. pneumoniae* is the most common bacterial pathogen, but gram-negative bacteria may also be problematic; *P. aeruginosa* pneumonia occurs most commonly in severely symptomatic children (CDC C3 category) and is often associated with acute respiratory failure and death. Rarely, bronchiectasis can develop and cause recurrent secondary infections. PCP is the most common opportunistic infection, but other pathogens, including CMV, *Aspergillus, Histoplasma*, and *Cryptococcus,* can cause pulmonary disease. Infection with common respiratory viruses, including respiratory syncytial virus, parainfluenza, influenza, and adenovirus, may occur simultaneously and have a protracted course and period of viral shedding from the respiratory tract. Pulmonary and extrapulmonary tuberculosis has been reported with increasing frequency in HIV-infected children, although it is considerably more common in HIV-infected adults.

CARDIOVASCULAR SYSTEM.

Subclinical cardiac abnormalities in HIV-infected children are common, persistent, and often progressive. A prospective study of young children with symptomatic HIV infection revealed that dilated cardiomyopathy and left ventricular hypertrophy were common; the 2-yr cumulative incidence of congestive heart failure was almost 5%. Children with encephalopathy or other AIDS-defining conditions have the highest rate of adverse cardiac outcomes. Resting sinus tachycardia has been reported in up to 64% and marked sinus arrhythmia in 17% of HIV-infected children. Hemodynamic instability occurs more frequently with advanced HIV disease and relates to the high frequency of severe autonomic neuropathy in patients with AIDS (up to 88%). Gallop rhythm with tachypnea and hepatosplenomegaly appear to be the best clinical indicators of CHF in HIV-infected children; anticongestive therapy is generally very effective, especially when initiated early. Electrocardiography and echocardiography are helpful in assessing cardiac function before the onset of clinical symptoms.

GASTROINTESTINAL AND HEPATOBILIARY TRACT.

Oral manifestations of HIV disease include erythematous or pseudomembranous candidiasis, periodontal disease (e.g., ulcerative gingivitis or periodontitis), salivary gland disease (i.e., swelling, xerostomia), and rarely ulcerations or oral hairy leukoplakia and ulcerations. Gastrointestinal tract involvement is common in HIV-infected children. A variety of pathogens can cause gastrointestinal disease, including bacteria (*Salmonella, Campylobacter*, MAC), protozoa (*Giardia, Cryptosporidium, Isospora*, microsporidia), viruses (CMV, HSV, rotavirus), and fungi (*Candida*). MAC and the protozoal infections are most severe and protracted in patients with severe CD4 cell depletion. Infections may be localized or disseminated and affect any part of the gastrointestinal tract from the oropharynx to the rectum. Oral or esophageal ulcerations, either viral in origin or idiopathic, are painful and often interfere with eating. Lesions that have negative viral cultures may respond to thalidomide, which is currently investigational, or to short courses of prednisone. **AIDS enteropathy,** a syndrome of malabsorption with partial villous atrophy not associated with a specific pathogen, has been postulated to be a result of direct HIV infection of the gut. Disaccharide intolerance is common in HIV-infected children with chronic diarrhea.

The most common symptoms of gastrointestinal disease are chronic or recurrent diarrhea with malabsorption, abdominal pain, dysphagia, and failure to thrive (FTT). Prompt recognition of weight loss or poor growth velocity in the absence of diarrhea is critical. Linear growth impairment is often correlated with the level of HIV viremia. Supplemental enteral feedings should be instituted, either by mouth or with nighttime nasogastric tube feedings in cases associated with more chronic growth problems; placement of a gastrostomy tube for nutritional supplementation may be necessary. The **wasting syndrome**, defined as a loss of >10% of body weight, is not as common as FTT in pediatric patients. However, the resulting malnutrition is associated with a grave prognosis and generally requires parenteral hyperalimentation.

Chronic liver inflammation evidenced by fluctuating serum levels of transaminases with or without cholestasis is relatively common, often without identification of an etiologic agent. Cryptosporidial cholecystitis is associated with abdominal pain, jaundice, and elevated gamma GT. In some patients, chronic hepatitis caused by CMV, hepatitis B or C, or MAC may lead to portal hypertension and liver failure. Several of the antiretroviral drugs or other drugs such as didanosine, protease inhibitors, and dapsone may also cause reversible elevation of transaminases.

Pancreatitis with increased pancreatic enzymes with or without abdominal pain, vomiting, and fever may be the result of drug therapy, e.g., pentamidine, didanosine, and lamivudine, or, rarely, opportunistic infections such as MAC or CMV.

RENAL DISEASE.

Nephropathy is an unusual presenting symptom of HIV infection, more commonly occurring in older symptomatic children. A direct effect of HIV on renal epithelial cells

has been suggested as the cause, but immune complexes, hyperviscosity of the blood (secondary to hyperglobulinemia), and nephrotoxic drugs are other possible factors. A wide range of histologic abnormalities has been reported, including focal glomerulosclerosis, mesangial hyperplasia, segmental necrotizing glomerulonephritis, and minimal change disease. Focal glomerulosclerosis generally progresses to renal failure within 6–12 mo, but other histologic abnormalities in children may remain stable without significant renal insufficiency for prolonged periods. Nephrotic syndrome is the most common manifestation of pediatric renal disease, with edema, hypoalbuminemia, proteinuria, and azotemia with normal blood pressure. Cases resistant to steroid therapy may benefit from cyclosporin therapy. Polyuria, oliguria, and hematuria have also been observed in some patients.

SKIN MANIFESTATIONS.

Many cutaneous manifestations seen in HIV-infected children are inflammatory or infectious disorders that are not unique to HIV infection. These disorders tend to be more disseminated and respond less consistently to conventional therapy than in the uninfected child. Seborrheic

---

dermatitis or eczema that is severe and unresponsive to treatment may be an early nonspecific sign of HIV infection. Recurrent or chronic episodes of herpes simplex virus, herpes zoster, molluscum contagiosum, flat warts, anogenital warts, and candidal infections are common and may be difficult to control.

Allergic drug eruptions are also common, in particular related to sulfonamides, and generally respond to withdrawal of the drug or to desensitization. Epidermal hyperkeratosis with dry, scaling skin is frequently observed, and sparse hair or hair loss may be seen in the later stages of the disease.

HEMATOLOGIC AND MALIGNANT DISEASES.

Anemia occurs in 20–70% of HIV-infected children, more commonly in children with AIDS. The anemia may be due to chronic infection, poor nutrition, autoimmune factors, virus-associated conditions (e.g., hemophagocytic syndrome, parvovirus B19 red cell aplasia), or adverse effect of drugs (e.g., zidovudine). In children with low erythropoietin levels, subcutaneous recombinant erythropoietin may be successful in treating the anemia.

Leukopenia occurs in almost one third of untreated HIV-infected children, and neutropenia often occurs. In some cases, antineutrophil antibodies are the cause, and treatment with intravenous immunoglobulin (IVIG) has been successful. Multiple drugs used for treatment or prophylaxis for opportunistic infections such as PCP, MAC, and CMV or antiretroviral drugs (e.g., zidovudine) may also cause leukopenia and/or neutropenia. In many cases, treatment with subcutaneous granulocyte colony-stimulating factor (GCSF) is successful.

Thrombocytopenia has been reported in 10–20% of patients. The etiology may be immunologic (i.e., circulating immune complexes or antiplatelet antibodies) or due to drug toxicity, or the cause may be unknown. Treatment with IVIG or anti-D offers temporary improvement in most cases. If ineffective, a 2–3 day course of high dose steroids (30?mg/kg/24?hr) may be an alternative. Antiretroviral therapy may also reverse thrombocytopenia. Deficiency of clotting factors (e.g., factors II, VII, IX) is not rare in children with advanced HIV disease and is often easy to correct (i.e., vitamin K). A novel disease of the thymus has been observed in a few HIV-infected children. These patients were found to have characteristic anterior mediastinal multilocular thymic cysts without clinical symptoms. Histologic examination shows focal cystic changes, follicular hyperplasia, and diffuse plasmocytosis and multinucleated giant cells. Spontaneous involution occurred in some cases.

In contrast to the more frequent occurrence in adults, malignant diseases have been reported infrequently in HIV-infected children, representing only 2% of AIDS-defining illnesses. Non-Hodgkins lymphoma, primary central nervous system lymphoma, and leiomyosarcoma are the most commonly reported neoplasms among HIV-infected children. Epstein-Barr virus is associated with most lymphomas and with all leiomyosarcomas. Kaposi sarcoma, which is caused by human herpesvirus 8 (Chapter 236), occurs frequently among HIV-infected adults but is exceedingly uncommon among HIV-infected children.

Diagnosis.

All infants born to HIV-infected mothers test antibody-positive at birth because of passive transfer of maternal HIV antibody across the placenta during gestation. Most uninfected infants (seroreverters) lose maternal antibody between 6–12 mo of age. Because a small proportion of uninfected infants continues to test HIV antibody–positive for up to 18 mo of age, positive IgG antibody tests cannot be used to make a definitive diagnosis of HIV infection in infants younger than this age. The presence of IgA or IgM anti-HIV in the infant's circulation can indicate HIV infection, because these immunoglobulin classes do not cross the placenta; however, detectable quantities of IgA anti-HIV are not generally produced until 3–6 mo of age, limiting its utility in young infants (sensitivity is 50–60% at 3 mo of age and 60–100% at 6 mo of age). IgM anti-HIV assays have been both insensitive and nonspecific and therefore are not valuable for clinical use. In any child >18 mo of age, demonstration of IgG antibody to HIV by a repeatedly reactive enzyme immunoassay (EIA) and confirmatory test (e.g., Western blot or immunofluorescence assay) establishes the diagnosis of HIV infection.

Several new rapid HIV tests are currently available with sensitivity and specificity similar to those of the standard EIA. Many of these new tests require only a single step that allows test results to be reported within 1–2?hr. Because the false-positive result of each test alone is high, the World Health Organization has recommended specific combinations of different rapid tests to confirm reactive HIV test results. Incorporating rapid HIV testing during delivery or immediately after birth allows HIV prevention counseling to those whose HIV status is unknown during pregnancy. Viral diagnostic assays, such as HIV DNA or RNA PCR, HIV culture, or HIV p24 antigen immune dissociated p24 (ICD-p24), are considerably more useful in young infants, allowing a definitive diagnosis in most infected infants by 1–6 mo of age. By 6 mo of age, the HIV culture and/or PCR identifies all infected infants. HIV DNA PCR is the preferred virologic assay in developed countries. Almost 40% of infected newborns have positive tests in the first 2 days of life, with >90% testing positive by 2 wk of

age. Plasma HIV RNA assays, which detect viral replication, may be more sensitive than DNA PCR for early diagnosis, but data are limited. HIV culture has similar sensitivity to HIV DNA PCR; however, it is more technically complex and expensive, and results are often not available for 2–4 wk compared to 2–3 days with PCR. The p24 antigen assay is cheaper, highly specific, and easy to perform, but it is less sensitive than the other virologic tests. It is not recommended for diagnosis of infection in infants <1 mo of age because of the high rate of false-positive results. In developing countries, the ICD-p24 test may be considered for older infants; however, if results are negative, it does not rule out infection.

Viral diagnostic testing should be performed within the first 2 days of life, at 1–2 mo of age, and at 4–6 mo of age; some also favor testing at age 14 days to maximize early detection of infected infants, if initiation of antiretroviral therapy is desired. A positive virologic assay (i.e., detection of HIV by PCR, culture, or p24 antigen) suggests HIV infection and should be confirmed by a repeat test on a second specimen as soon as possible. A diagnosis of HIV infection can be made with two positive virologic tests obtained from different blood samples.

Infants who have negative virologic assays initially should be retested at the intervals outlined above. Although the perinatal use of prophylactic zidovudine to prevent vertical transmission has not affected the predictive value of viral diagnostic testing, the effect of more intensive antiviral combinations (e.g., protease inhibitors) in pregnant women on the accuracy of the infant's viral tests is unknown. HIV infection can be reasonably excluded if an infant has had at least two negative virologic tests at age =1 mo of age with at least one test performed at =4 mo of age. In older infants and children, two or more negative HIV antibody tests performed at least 1 mo apart past 6 mo of age in the absence of hypogammaglobulinemia or clinical evidence of HIV disease can reasonably exclude HIV infection. The infection can be excluded definitively if the same parameters are met when the infant is at least 18 mo of age.

For infants born to HIV-infected mothers, who should be prescribed zidovudine perinatal prophylaxis, a complete blood count, differential leukocyte count, and platelet count should be performed at 4 wk of age. If the child is found to be HIV-infected or if the HIV status is not clear, these tests should be continued every 1–3 mo to assess the hematologic effect of the disease and its treatment (e.g., prophylactic TMP-SMZ and antiretroviral therapy). CD4 and CD8 lymphocyte counts should be performed at 1 and 3 mo of age. If the child is HIV-infected or the HIV status is not clear, the test should be repeated every 3 mo starting at 6 mo of age. The frequency of the test should be increased (i.e., every 4–6 wk) if the CD4 lymphocyte count or percentage declines rapidly.

Treatment.

The currently available therapy does not eradicate the virus and cure the patient; it only suppresses the virus for extended periods of time and changes the course of the disease to a chronic process. Decisions about antiretroviral therapy for pediatric HIV-infected patients are based on the magnitude of viral replication (i.e., viral load), CD4 lymphocyte count or percentage, and clinical condition. Because antiretroviral therapy changes as new drugs become available, decisions regarding therapy should be made in consultation with an expert in pediatric HIV infection. Although early treatment trials consisted of single or dual drug therapy, more recent trials have uniformly confirmed the superiority of three or more drug combination therapy using virologic, immunologic, and clinical end-points. Plasma viral load monitoring and measurement of CD4 values have made it possible to implement rational treatment strategies for viral suppression as well as to assess the efficacy of a particular drug combination. The following principles form the basis for antiretroviral treatment: (1) uninterrupted HIV replication causes destruction of the immune system and progression to AIDS; (2) the magnitude of the viral load predicts the rate of disease progression, and the CD4 cell count reflects the risk of opportunistic infections and HIV infection complications; (3) potent combination therapy that suppresses HIV replication to an undetectable level restricts the selection of antiretroviral-resistant mutants; drug-resistant strains are the major factor limiting successful viral suppression and delay of disease progression; (4) the goal of sustainable suppression of HIV replication is best achieved by the simultaneous initiation of combinations of antiretroviral agents to which the patient has not been exposed previously and which are not cross-resistant to drugs with which the patient has been treated previously; (5) adherence to the complex drug regimens is crucial for a successful outcome.

COMBINATION THERAPY.

Antiretroviral drugs licensed as of 2002 (Table 254–3) are categorized based on their ability to inhibit the HIV reverse transcriptase or protease enzymes. Within the reverse transcriptase inhibitors, a further subdivision can be made: nucleoside (or nucleotide) reverse transcriptase inhibitors (NRTIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs). The NRTIs have a similar structure to the building blocks of the

TABLE 254-3 -- Antiretroviral Drugs Available in 2003 and Some of Their Toxicities[*]

	Drug Toxicity	
	Most frequent	***Unusual***
Reverse Transcriptase Inhibitors (NRTI)[†]		
Abacavir (ABC)	Gastrointestinal intolerance, headache, rash	Hypersensitivity, pancreatitis
Didanosine (ddI)	Gastrointestinal intolerance, abdominal pain	peripheral neuropathy, pancreatitis, lactic acidosis
Lamivudine (3TC)	Headache, fatigue, gastrointestinal intolerance, rash	Pancreatitis, peripheral neuropathy, neutropenia, lactic acidosis
Stavudine (d4T)	Headache, gastrointestinal intolerance	Rash, peripheral neuropathy, pancreatitis, lactic acidosis
Tenofavir (TNF)	Gastrointestinal complaints, asthenia, headache	Hepatomegaly, lactic acidosis, bone abnormalities

Zalcitabine (ddC)	Gastrointestinal intolerance, headache, malaise	Pancreatitis, oral/esophageal ulcers, peripheral neuropathy, lactic acidosis
Zidovudine (ZDV)	Anemia, granulocytopenia, headache	Hepatotoxicity, myopathy, lactic acidosis
Non-nucleoside Reverse Transcriptase Inhibitors (NNRTI)		
Delavirdine§ (DLV)	Rash, gastrointestinal complaints, headache, fatigue	Abdominal pain, headache, fatigue
Efavirenz (EFV)	Rash, CNS symptoms	Hepatotoxicity, pancreatitis
Nevirapine§ (NVP)	Rash, gastrointestinal complaints, headache, fatigue	Hepatotoxicity, hypersensitivity
Protease Inhibitors (PI)‡		
Amprenavir (APV)	Gastrointestinal intolerance, rash	Perioral paresthesia, headache
Indinavir§ (IDV)	Gastrointestinal intolerance, hyperbilirubinemia	Nephrolithiasis, dizziness
Lopinavir¶ (LPV)	Gastrointestinal intolerance, headache, asthenia	Rash, hepatotoxicity
Nelfinavir§ (NFV)	Diarrhea, abdominal pain	Asthenia, rash, exacerbation of chronic liver disease
Ritonavir§ (RTV)	Gastrointestinal intolerance, abdominal pain, anorexia, headache	Elevated transaminases, perioral paresthesias, hepatotoxicity
Saquinavir§ (SQV)	Diarrhea, abdominal pain, headache, nausea	Exacerbation of chronic liver disease, perioral paresthesia, rash

** Not all adverse effects are listed. See prescribing information in package inserts.*
†Combinations of ZDV and 3TC (Combivir) and ZDV, 3TC, and ABC (Trizivir) are available for adolescents and adults.
§Significant drug-drug interactions; some may be life-threatening.
‡All the protease inhibitors can cause hyperglycemia, diabetes, lipodystrophy, hemolytic anemia, and spontaneous bleeding episodes in hemophiliacs.
¶Always in combination with a low-dose ritonavir.

DNA (e.g., thymidine, cytosine). By incorporating themselves into the DNA, they act like a chain terminator and block further incorporation of nucleosides, which prevent viral DNA synthesis. Among the NRTIs, thymidine analogs (stavudine [d4T] and zidovudine [ZDV]) are found in higher concentrations in activated or dividing cells, and nonthymidine analogs (didanosine [ddI], lamivudine [3TC], and dideoxycytidine [ddC]) have more activity in resting cells. Activated cells are thought to produce >99% of the population of HIV virons. In contrast, resting cells account for <1% of the population, but may serve as a reservoir of HIV. Suppression of replication in both populations is thought to be an important component of long-term viral control.

NNRTIs (e.g., nevirapine and efaverenz) act differently than the NRTIs. They attach to the reverse transcriptase and restrict its motility, which reduces the activity of the enzyme. Protease inhibitors (e.g., ritonavir, nelfinavir, saquinavir) are potent agents that are active farther along in the viral life cycle. They bind to the site where the viral long polypeptides are cut to individual, mature, and functional core proteins, which produces the infectious virons before they leave the cell.

While the principal site of viral replication is lymphoid tissue, sanctuary sites such as the CNS may harbor residual virons with the potential of being a source of local or persistent disease. Impaired penetration of drugs to these compartments could result in development of resistance. Although data on CNS penetration of antiviral agents are presently limited, ZDV, d4T, and 3TC appear to achieve inhibitory concentrations in the CNS. Indinavir and nevirapine also penetrate the CSF, but other protease inhibitors are actively transported out of the CNS, thereby limiting their potential efficacy.

By targeting different points in the viral life cycle and stages of cell activation, and delivering drug to all tissue sites, maximal viral suppression may be feasible. Combinations of three drugs, such as a thymidine analog NRTI, a nonthymidine analog NRTI (to suppress replication in both active and resting cells), and a protease inhibitor or an NNRTI have been shown in adults and in children to produce prolonged viral suppression. Additional regimens such as triple NRTIs (i.e., abacavir, zidovudine, and

lamivudine) or lopinavir/ritonavir in combination with two NRTIs or one NRTI and an NNRTI are also recommended as alternatives. Although not ideal, less potent combinations (e.g., dual NRTIs, ritonavir with stavudine, amprenavir with abacavir) may be considered in special situations when there are concerns about adherence to a complex drug regimen or when the patient and/or family prefer an alternative regimen. Combination treatment increases the rate of toxicities (see Table 254–3), and complex drug-drug interactions exist among many of the antiretroviral drugs. Most NNRTI and protease inhibitor drugs are inducers or inhibitors of the cytochrome P450 system. The protease inhibitors are particularly likely to have serious interactions with multiple drug classes, including nonsedating antihistamines, psychotropic, vasoconstrictor, antimycobacterial, cardiovascular, analgesic, and gastrointestinal drugs (e.g., cisapride). Whenever new medications are added to an antiretroviral treatment, especially a protease inhibitor-containing regimen, a pharmacist and/or HIV specialist should be consulted to address possible drug interactions. Recently the inhibitory effect of ritonavir (a protease inhibitor) on the cytochrome P450 system was exploited, and small doses of the drug are added to several other protease inhibitors (e.g., lopinavir, indinavir, saquinavir) to slow their metabolism by the P450 system and to improve their pharmacokinetic profile. This provides more effective drug levels with less toxicity and less frequent dosing.

ADHERENCE.

Assessment of the likelihood of adherence to treatment is an important factor in deciding whether and when to initiate therapy. Numerous studies have shown that

compliance of <80–90% results in less successful suppression of the viral load. In addition, poor adherence to prescribed medication regimens results in subtherapeutic drug concentrations and enhances development of resistance, particularly with protease inhibitors and NNRTI drugs. Combination antiretroviral regimens require multiple daily doses and are often unpalatable, requiring extreme dedication on the part of the care provider and child; this makes participation of the family in the decision to initiate therapy essential. Intensive education on the relationship of drug adherence to viral suppression, training on drug administration, frequent follow-up visits, and commitment of the caregiver and the patient (despite the inconvenience of side effects, dosing schedule, and so on) are critical for successful antiviral treatment.

INITIATION OF THERAPY.

HIV-infected children with symptoms (clinical category A, B, or C) or with evidence of immune dysfunction (immune category 2 or 3) should be treated with antiretroviral therapy, regardless of age or viral load. Children <1 yr of age are at high risk for disease progression, and immunologic and virologic tests to identify those likely to develop rapidly progressive disease are less predictive than in older children. Therefore, such infants should be treated with antiretroviral agents as soon as the diagnosis of HIV infection has been confirmed, regardless of clinical or immunologic status, or viral load. Data suggest that HIV-infected infants who are treated before the age of 3 mo of age control their HIV infection better than infants whose antiretroviral therapy started later than 3 mo of age.

Many clinicians advocate treating asymptomatic children =1 yr of age to prevent immunologic deterioration. However, when there are concerns regarding drug adherence, safety, and durability of antiretroviral response, some providers elect to delay treatment in the immunologically normal child >1 yr with a low viral load (<50,000 copies/mm^3) for whom the risk for clinical progression is low. Such children should be monitored regularly for evidence of virologic, immunologic, or clinical progression, at which point therapy should be initiated.

DOSING.

Data on antiretroviral drug dosages for neonates are often limited. Because of the immaturity of the neonatal liver, premature infants and newborns often require an increase in the dosing interval of drugs primarily cleared through hepatic metabolism (glucuronidation).

Adolescents should have antiretroviral dosages prescribed on the basis of Tanner staging of puberty rather than on the basis of age. During early puberty (Tanner stage I, II, and III), pediatric dosing ranges should be used, whereas adolescents in late puberty (Tanner stage IV and V) should follow adult dosing schedules.

CHANGING ANTIRETROVIRAL THERAPY.

Therapy should be changed when the current regimen is judged ineffective as evidenced by increase in viral load, deterioration of the CD4 cell count, or clinical progression. Development of toxicity or intolerance to drugs is another reason to consider a change in therapy. When a change is considered, the patient and family should be reassessed for adherence problems. While considering possible new drug choices, potential cross-resistance should be addressed. In addition, few patients who have virologic failure may still demonstrate elevated CD4 cell counts (**discordant response**). Impaired replication ability of the resistant virus and autoimmunization with enhanced cytotoxic T lymphocyte (CTL) effect are some of the reasons for this discordant response. Ideally, all drugs should be changed. However, in many situations (e.g., previous antiretroviral experience, intolerance, toxicity) this is not possible, and, therefore, at least two drugs should be changed. If an alternative regimen that is likely to suppress the viral load is not available in patients with discordant response, the same regimen should be continued to maximize the clinical and immunologic benefits.

MONITORING ANTIRETROVIRAL THERAPY.

Virologic and immunologic surveillance (using HIV RNA copy number and CD4 lymphocyte count or percentage) as well as clinical assessment should be performed regularly in children taking antiretroviral therapy. Initial virologic response (i.e., at least five fold [0.7 $\log_{10}$] reduction in viral load) should be achieved within 4 wk of initiating antiretroviral therapy. The maximum response to therapy usually occurs within 12–16 wk. Thus, HIV RNA levels should be measured at 4 wk and 3–4 mo after therapy initiation. Once an optimal response has occurred, viral load should then be measured at least every 3–6 mo. If the response is unsatisfactory, another viral load should be performed as soon as possible to verify the results before a change in therapy is considered. The CD4 cells respond more slowly to successful treatment and, therefore, can be monitored less frequently (i.e., every 3–4 mo). Potential toxicity should be monitored closely for the first 8–12 wk, and if no clinical or laboratory toxicity is documented, a follow-up every 2–3 mo is adequate. Several toxicities have been causing increasing concern regarding antiretroviral use (especially protease inhibitors). These toxicities include lipodystrophy (e.g., redistribution of body fat and elevation of cholesterol and triglyceride concentrations), insulin intolerance, lactic acidosis, and severe hepatomegaly with steatosis.

RESISTANCE TO ANTIRETROVIRAL THERAPY.

The high mutation rate of HIV (mainly due to the absence of error-correcting mechanisms) severely impairs the success of antiretroviral therapy. Failure to reduce the viral load to less than 50 copies/mL increases the risk of developing resistance. Recent data suggest that even effectively treated patients are not completely suppressing viral replication and that persistence of HIV transcription and evolution of envelope sequences continue in the latent cellular reservoirs. The accumulation of resistance mutation progressively diminishes the potency of the antiretroviral therapy and challenges the physician to find new regimens. Testing for drug resistance when devising a new regimen is rapidly becoming the standard of care. Two types of tests are available. The **phenotypic assay** that measures the virus susceptibility in various concentrations of the drug and the **genotypic assay** that predicts the virus susceptibility from mutations identified on the HIV genome isolated from the patient. Several studies have shown that the treatment success was higher in patients whose antiretroviral therapy was guided by genotype or phenotype testing.

SUPPORTIVE CARE.

Even before the new antiretroviral drugs were available, a significant impact on the quality of life and survival of HIV-infected children was achieved when supportive care was given. A multidisciplinary team approach is desirable for successful management. Close attention should be paid to nutrition status, which is often delicately balanced and may require aggressive preemptive intervention (e.g., nasogastric or gastric feedings or parenteral nutrition) to achieve adequate caloric and protein intake. Painful oropharyngeal lesions and dental caries are frequent and may interfere with eating; routine dental evaluations and careful attention to oral hygiene should be encouraged. Development should be evaluated regularly with provision of necessary physical, occupational, and/or speech therapy. Recognition of pain in the young child may be difficult, and effective pharmacologic and nonpharmacologic protocols for pain management should be instituted, especially during the terminal phase of the disease.

All HIV-exposed and infected children should receive standard pediatric immunizations. In general, live oral polio vaccine and live bacterial vaccines (e.g., BCG) should not be given (Fig. 254–2). Varicella and MMR vaccines are recommended for children in immune categories 1 and 2, but neither varicella nor MMR should be given to severely immunocompromised children (immune category 3). Of note, prior immunizations do not always provide protection, as evidenced by outbreaks of measles and pertussis in immunized HIV-infected children.

Prophylactic regimens are integral for the care of HIV-infected children. All infants between 6 wk–1 yr of age either (1) born to HIV-infected mothers or (2) proved to be HIV-infected should receive prophylaxis regardless of the CD4 count or percentage (see Table 254–3). When the child is >1 yr of age, prophylaxis should be given according to the CD4 lymphocyte count (Table 254–4). The best prophylactic regimen is 150/750?mg/m^2 /24?hr of TMP-SMZ given as one or two daily doses 3 days per week. If the patient experiences a mild allergic reaction (e.g., rash), desensitization is usually successful to allow daily TMP-SMZ prophylaxis. For severe adverse reactions to TMP-SMZ, alternative therapies include dapsone, atovaquone, or aerosolized or intravenous pentamidine.

Prophylaxis against MAC should be offered to HIV-infected children with advanced immunosuppression (i.e., CD4 lymphocyte count <500 cells/mm^3 in children <1 yr of age, <75 cells/mm^3

Figure 254-2 Differences in immunization schedule for HIV-infected children from the routine childhood immunization schedule. * See text. † Revaccination is recommended every year. ‡ Revaccination with pneumococcal polysaccharide vaccine (PPV) every 5 yr. § Contraindicated in children with AIDS or immune category 3 (see Table 254–1). ? Recommended routinely for all HIV-infected children.

in children 1–6 yr of age, and <50 cells/mm^3 in children >6 yr of age). The drugs of choice are clarithromycin (7.5?mg/kg bid PO) or azithromycin (20?mg/kg once a week PO or 5?mg/kg once daily PO).

Primary prophylaxis against opportunistic infections may be discontinued if patients have experienced sustained (>6 mo duration) immune reconstitution with HAART. Even if patients have had opportunistic infections such as PCP or DMAC, it may also be possible to discontinue secondary prophylaxis if immune reconstitution has been sustained.

Some experts recommend IVIG to prevent recurrent serious bacterial infections for HIV-infected children who (1) have suffered from at least two documented serious bacterial infections within 1 yr, (2) have laboratory-documented inability to make antigen-specific antibodies, or (3) are hypogammaglobulinemic. The dose is 400?mg/kg every 4 wk.

All HIV-exposed children should have skin testing (i.e., 5TU PPD) for tuberculosis at 1 yr of age and be retested every 2 yr. If the child is living in close contact with a person with tuberculosis, he or she should be tested annually. To reduce the incidence of other potential infections, parents should be counseled about (1) the importance of good hand washing, (2) avoiding raw or undercooked food (salmonella), (3) avoiding drinking or swimming in lake or river water or being in contact with young farm animals (*Cryptosporidium*), and (4) the risk of playing with pets (e.g., *Toxoplasma* and *Bartonella* from cats, *Salmonella* from reptiles).

Because of the frequent changes in these guidelines, physicians providing care to few HIV-exposed or infected children should periodically consult physicians with expertise in pediatric HIV infection.

Prognosis.

The improved understanding of the pathogenesis of HIV infection in children and the availability of more effective antiretroviral drugs have changed the prognosis considerably. In developed countries where early diagnosis leads to prompt antiretroviral therapy, progression of the disease and mortality rate have diminished. HIV-infected children live longer with improved quality of life. In general, the best single prognostic indicator is the plasma viral load. Although there is no threshold above which rapid progression can be predicted, it is unusual to see rapid progression in an infant with a viral load <100,000 copies/mL. In addition, a high viral load (>100,000 copies/mL)

TABLE 254-4 -- Recommendations for PCP Prophylaxis and CD4 Monitoring for Human Immunodeficiency Virus (HIV)-Exposed Infants and HIV-Infected Children, By Age and HIV-Infection Status

Age/HIV-infection Status	PCP Prophylaxis	CD4 Monitoring
Birth to 4–6 wk, HIV exposed	No prophylaxis	1 mo

4–6 wk to 4 mo or HIV exposed 4–12 mo	Prophylaxis	3 mo
HIV-infected or indeterminate	Prophylaxis	6, 9, and 12 mo
HIV infection reasonably excluded[*]	No prophylaxis	None
1–5 yr, HIV infected	Prophylaxis if:	Every 3–4 mo[†]
	CD4 count is <500 cells/µL or	
	CD4 percentage is <15%[‡] [§]	
6–12 yr, HIV infected	Prophylaxis if:	Every 3–4 mo[†]
	CD4 count is <200 cells/µL or	
	CD4 percentage is < 15%[§]	

From Centers for Disease Control and Prevention: 1995 revised guidelines for prophylaxis against Pneumocystis carinii pneumonia for children infected with or perinatally exposed to human immunodeficiency virus. MMWR 1995; 44(RR-4):1–18.

**HIV infection can be reasonably excluded among children who have had 2 or more negative HIV diagnostic tests (i.e., HIV culture or PCR), both of which are performed at = 1 mo of age and one of which is performed at = 4 mo of age, or 2 or more negative HIV IgG antibody tests performed at > 6 mo of age among children who have no clinical evidence of HIV disease.*

†More frequent monitoring (e.g., monthly) is recommended for children whose CD counts or percentages are approaching the threshold at which prophylaxis is recommended.

‡Children 1–2 yr of age who were receiving PCP prophylaxis and had a CD4 count of <750 cells/µL or percentage of <15% at <12 mo of age should continue prophylaxis.

§Prophylaxis should be considered on a case-by-case basis for children who might otherwise be at risk for PCP, such as children with rapidly declining CD4 counts or percentages or children with Category C conditions. Children who have had PCP should receive lifelong PCP prophylaxis.

over time is associated with greater risk for disease progression and death. CD4 lymphocyte percentage is another prognostic indicator and the mortality rate is higher in patients with CD4 lymphocyte percentage <15%. To define prognosis more accurately, the use of changes in both markers (i.e., CD4 lymphocyte percentage and plasma viral load) is recommended.

In developing countries where antiretroviral therapy and sophisticated diagnostic tests are scarce, a clinical staging system can be used to predict progression of disease. The suggested clinical staging is quite similar to the classification recommended in the 1994 revised CDC classification. Children with opportunistic infections (e.g., PCP, MAC), encephalopathy, or wasting syndrome have the worst prognosis, with 75% dying before 3 yr of age. Persistent fever and/or oral thrush, serious bacterial infections (e.g., meningitis, pneumonia, sepsis), hepatitis, persistent anemia (<8.0?g/dL), and/or thrombocytopenia (<100,000/mm^3) also suggest a poor outcome, with >30% of such children dying before age 3 yr of age. In contrast, lymphadenopathy, splenomegaly, hepatomegaly, lymphoid interstitial pneumonitis, and parotitis are indicators of a better prognosis.

Prevention.

Interruption of perinatal transmission from mother-to-child has been achieved by administering ZDV chemoprophylaxis to the pregnant woman (100?mg five times/24?hr PO, started as early as 4 wk of gestation) and continued during delivery (2?mg/kg loading dose IV followed by 1?mg/kg/hr IV) and in the newborn for the first 6 wk of life (2?mg/kg q 6?hr PO). In the developed world, such therapy has been documented to decrease the rate of perinatal HIV-1 transmission to <8%. Toxicity from ZDV therapy in both mothers and infants is minimal. Although this treatment was first given to untreated, asymptomatic, and immunologically intact women, epidemiologic data have confirmed the efficacy of ZDV chemoprophylaxis for reduction of perinatal transmission to offspring of women with advanced disease, low CD4 counts, and prior ZDV therapy. Rates of perinatal transmission have been as low as 2% among women who received HAART and all three components of the ZDV regimen, even in women with advanced HIV-1 disease. Even though this regimen is effective, it is logistically complex and expensive. A short-term regimen (300?mg twice daily from 36 wk gestation and 300?mg every 3?hr during delivery) offers a simpler, effective (almost 50% reduction in transmission), and less expensive regimen that can be used in areas where the long-term regimen is difficult to implement. Retrospective data suggest that even if a mother has received no antiretroviral therapy during gestation or delivery, the 6-wk component of the ZDV prophylactic regimen instituted for the newborn as soon as possible after delivery and preferably within 12–24?hr of birth results in a meaningful reduction of transmission rate. Full-term infants should be given ZDV at a dose of 2?mg/kg q 6?hr for 6 wk. For preterm infants, the dose should be 1.5?mg/kg orally or intravenously q 12?hr for the first 2 wk of life and then increased to 2?mg/kg q 8?hr.

A study evaluating the efficacy of oral nevirapine, a non-nucleoside reverse transcriptase inhibitor, given once to women in labor and once to the infant during the first 48–72?hr of life, capitalizes on the prolonged half-life of this drug. It has been shown to reduce perinatal transmission by 50% in Africa, providing a simple and highly cost-effective regimen for developing countries. Combinations of drugs more potent than ZDV are being used for treatment of HIV-1 infection in non-pregnant women; the role of these agents in prevention of perinatal transmission is under investigation. Decisions regarding use and choice of antiretroviral drugs during pregnancy are complex and require coordination between the HIV-specialist and the obstetrician. However, ZDV should be included as a component of all perinatal regimens, because ZDV is the only drug that has been demonstrated to prevent perinatal transmission.

Now that it is clear that perinatal transmission can be reduced dramatically by treating pregnant mothers, a compelling argument can be made for prenatal identification of HIV-1 infection in the mother. The benefit of therapy, both for the mother's health and to prevent transmission to the infant, cannot be overemphasized. The recommended universal prenatal HIV-1 counseling and HIV-1 testing with consent for all pregnant women has reduced the number of new infections dramatically in many areas of the United States. When risk assessment alone is used to decide which women warrant perinatal counseling and testing, a substantial number of women do not receive these services. For women not tested during pregnancy, the use of

rapid HIV antibody testing during labor, or in the first day of life for the infant is a way to provide perinatal prophylaxis to an additional group of at-risk infants.

Prevention of sexual transmission involves avoiding the exchange of bodily fluids. In sexually active adolescents, condoms should be an integral part of programs to reduce sexually transmitted diseases. Unprotected sex with older partners or with multiple partners and use of illicit drugs is common among HIV-1–infected adolescents, which increases their risk. Educational efforts about avoidance of risk factors are essential for older school-aged children and adolescents and should begin before the onset of sexual activity.

Chapter 255 - Human T-Cell Lymphotropic Viruses Types I and II

Hal B. Jenson

Human T-cell lymphotropic viruses type I (HTLV-I) and type II (HTLV-II), members of the *Oncovirinae* subfamily of the Retroviridae family, are single-stranded RNA viruses that encode reverse-transcriptase, an RNA-dependent DNA polymerase that transcribes the single-stranded viral RNA into a double-stranded DNA copy. The circular DNA is transported into the nucleus, where it is integrated into chromosomal DNA (provirus), evading the usual mechanisms of immune surveillance and resulting in lifelong infection. HTLV-I and HTVL-II both transform lymphocytes in vitro and share approximately 65% genome homology. Serologic assays used in early epidemiologic studies were unable to differentiate between the two viruses, but more recent Western immunoblot assays as well as polymerase chain reaction may be used to discriminate infection with these two viruses.

Epidemiology and Clinical Manifestations.

HTLV-I was the first human retrovirus to be associated with cancer, as the cause of adult T-cell leukemia/lymphoma (ATL). HTLV-I is also associated with several nonmalignant conditions including the neurodegenerative disorder **HTLV-I-associated myelopathy (HAM),** also known as **tropical spastic paraparesis (TSP)** and currently termed HAM/TSP. The geographic epidemiology of ATL and HAM/TSP are similar. HTLV-I is endemic in southern Japan (where more than 25% of adults are seropositive), Asia, areas of the Caribbean, and in parts of sub-Saharan Africa and Central and South America. There is microclustering with marked variability within small geographic regions. The seroprevalence of HTLV-I and HTLV-II in the United States in the general population is 0.01% for each virus, with higher rates with increasing age. HTLV-I infection correlates greatest with birth from or sexual contact with persons from endemic areas of Japan or the Caribbean, with overall higher prevalence in females and African-American and Hispanic persons. HTLV-II infection correlates with intravenous illicit drug use, with an overall prevalence of approximately 18% in one study of drug users in the United States, often with concomitant HTLV-I or HIV infection.

HTLV-I and II are transmitted as cell-associated viruses through sexual contact, contaminated blood products, intravenous illicit drug use, and perinatally, usually via breast milk. Studies in Japan have shown that approximately 25% of children born to infected mothers become infected; more than 90% of HTLV-I–infected children have HTLV-I–infected mothers. Perinatal HTLV-I transmission occurs primarily via breast-feeding from infected mothers, with a threefold increased risk of transmission with breast-feeding for more than 6 mo. Intrauterine and intrapartum transmission probably account for less than 5% of vertical transmission. HTLV-II, like HTLV-I, may also be transmitted via breast-feeding but has a lower breast milk transmission rate of approximately 14%.

T-CELL LEUKEMIA/LYMPHOMA.

The age distribution of ATL peaks at approximately 50 yr, underscoring the long latent period of HTLV-I infection. HTLV-I–infected persons remain at risk for ATL even if they move to an area of low HTLV-I prevalence, with a lifetime risk of ATL of 2–4%. HTLV-I infects $CD4^{+}$ lymphocytes with a spectrum of disease from subclinical lymphoproliferation that may spontaneously resolve in approximately half of cases, or progress to chronic leukemia, lymphoma, and culminate in acute ATL. Chronic, low-grade, HTLV-I–associated lymphoproliferation (pre-ATL) may persist for years with abnormal lymphocytes with or without peripheral lymphadenopathy before progressing to the acute form. Most cases of ATL are associated with monoclonal integration of HTLV-I provirus into the cellular genome. ATL is characterized by hypercalcemia, lytic bone lesions, lymphadenopathy that spares the mediastinum, hepatomegaly, splenomegaly, cutaneous lymphomas, and opportunistic infections. Leukemia may occur with circulating polylobulated malignant lymphocytes possessing mature T-cell markers, called flower cells. Conventional chemotherapy is not curative, and relapses are common, with median survival of 11 mo from diagnosis.

Sequences of the HTLV-I tax gene have been found in lesions of mycosis fungoides, a T-cell lymphoma characterized by proliferation of atypical lymphocytes preferentially in the skin. Patients are usually middle-aged and present with diffuse hypopigmented plaques and patches. Mycosis fungoides may be caused by HTLV-I or a closely related virus.

MYELOPATHY.

HAM/TSP occurs in <1% of persons with HTLV-I infection, usually developing during middle age. It is characterized by gradual onset and slowly progressive neurologic degeneration of the corticospinal tracts and, to a lesser extent, the sensory system. Approximately 50% of patients with HAM/TSP have HTLV-I infection; other postulated causes include chronic intoxication of cyanogenic glycosides from the consumption of cassava or from amino acid dietary deficiencies.

HAM/TSP is more common in women than in men, and has a relatively short incubation period after HTLV-1 infection: 1–4 yr compared with 40–60 yr for ATL. Clinical manifestations include permanent evolution of lower extremity spasticity or weakness, lower back pain, and hyperreflexia of the lower extremities with an extensor plantar response. The bladder and intestines may become dysfunctional,

and men may become impotent. Some patients may have dysesthesias of the lower extremities with diminished sensation to vibration and pain. Upper extremity function and sensation, cranial nerves, and cognitive function are usually preserved. The cerebrospinal fluid may have a mildly elevated protein and a mild monocytic pleocytosis. Neuroimaging studies are normal or show periventricular lesions in the white matter. Treatment with corticosteroids or danazol, a synthetic androgen, has been reported to benefit some patients.

HTLV-II.

HTLV-II was originally identified in patients with hairy cell leukemia, although most patients with hairy cell leukemia are seronegative for HTLV-II infection. HTLV-II has been rarely isolated from patients with leukemias or with myelopathies resembling HAM/TSP, but there is limited evidence of disease specifically associated with HTLV-II infection.

Prevention.

Routine antibody testing of all blood products using HTLV-I viral lysate began in the United States in 1988, which missed 30–58% of HTLV-II infections, but combination HTLV-I/II antibody testing was implemented in 1997. Formula feeding of infants of HTLV-I–infected mothers is an effective means to control endemic HTLV-I transmission in developed countries. No vaccine is available.

Chapter 256 - Primary Amebic Meningoencephalitis

Martin E. Weisse
Stephen C. Aronoff

Naegleria, Acanthamoeba, and *Balamuthia* are small free-living amebas that cause human amebic meningoencephalitis. Amebic meningoencephalitis has two distinct clinical presentations. The more common is an acute, usually fatal **amebic meningitis** that is caused by *Naegleria* and that occurs in previously healthy children and young adults. The second form, **granulomatous amebic meningoencephalitis,** is caused by *Acanthamoeba* and *Balamuthia* and is a more indolent infection that is more likely to occur in immunocompromised individuals.

Etiology.

Naegleria is an ameboflagellate that can exist as cysts, trophozoites, and transient flagellate forms. Temperature and environmental nutrient and ion concentrations are the major factors determining which stage of the ameba is found in the environment. Trophozoites are the only stages that are invasive, although cysts are potentially infective because they can convert to the vegetative form very quickly under the proper environmental stimuli. There are several species of *Naegleria*, of which only *N. fowleri* has been shown to be pathogenic for humans.

In contrast to *Naegleria* organisms, *Acanthamoeba* has only a cyst and trophozoite form, of which only the trophozoite form is invasive. Of the 13 species of *Acanthamoeba*, 7 are human pathogens. *A. castellani, A. culbertsoni, A. polyphaga*, and *A. rhysodes* have all been recovered from human infections of both the eye and the central nervous system (CNS). *A. astronyxis* and *A. palestinensis* have only been implicated in CNS infections. *A. hatchetti* has only been isolated from the eye. Granulomatous amebic encephalitis from *Acanthamoeba* has been reported worldwide. Most of the cases reported have been associated with immunomodulating conditions such as HIV infection, diabetes mellitus, alcoholism, or radiation therapy.

Cases of *Acanthamoeba* keratitis have usually followed incidents of corneal trauma involving flushing with contaminated water or have occurred in contact lens wearers whose lenses have been contaminated with *Acanthamoeba*.

In 1990 the ameba *Balamuthia mandrillaris* was isolated from the brain of a mandrill baboon that died of meningoencephalitis. On the basis of immunofluorescent staining results, this same organism has been implicated in 35 cases of granulomatous amebic encephalitis that had formerly been without definitive diagnosis but were attributed to *Acanthamoeba*. Although the clinical presentation is similar to infection with *Acanthamoeba*, most patients have no known immunocompromising condition.

Epidemiology.

The free-living amebas have a worldwide distribution. *Naegleria* has been isolated from a variety of freshwater sources, including ponds and lakes, domestic water supplies, hot springs and spas, thermal discharge of power plants, and groundwater and occasionally from the nasal passages of healthy children. *Acanthamoeba* has been isolated from soil, mushrooms and vegetables, brackish water, and seawater, as well as most of the freshwater sources for *Naegleria.*

Naegleria meningoencephalitis was first reported in the United States in 1966, and since that time infection has been reported from every continent. Most of the cases have been contracted during the summer months by previously healthy individuals

with a history of swimming in or contact with fresh water before their illness. Usually only 1–2 cases are reported per year in the United States, with a peak of 8 cases reported in 1980. Most of the reports have come from the southern and southwestern states, with occasional infections occurring in the Midwest and East.

Pathogenesis.

The free-living amebas enter the nasal cavity by inhalation or aspiration of dust or water contaminated with trophozoites or cysts. *Naegleria* gains access to the CNS through the olfactory epithelium and migration via the olfactory nerve to the olfactory bulbs, which are located in the subarachnoid space bathed by the cerebrospinal fluid (CSF). This space is richly vascularized and is the route of spread to other areas of the CNS. In addition to evidence of widespread cerebral edema and hyperemia of the meninges, the olfactory bulbs are necrotic, hemorrhagic, and surrounded by a purulent exudate. Microscopically, the gray matter is the most severely affected, with severe involvement in all cases. Fibrinopurulent exudate may be found throughout the cerebral hemispheres, brain stem, cerebellum, and upper portions of the spinal cord. Pockets of trophozoites may be seen in necrotic neural tissue, usually in the perivascular spaces of arteries and arterioles. No cysts are present in the CNS.

The route of invasion and penetration in cases of granulomatous amebic meningoencephalitis, caused by *Acanthamoeba* and *Balamuthia*, is hematogenous,

probably originating from a primary focus in the skin or lungs. Pathologic examination reveals granulomatous encephalitis, with multinucleated giant cells mainly in the posterior fossa structures, basal ganglia, bases of the cerebral hemispheres, and cerebellum. Both trophozoites and cysts may be found in the CNS lesions, primarily located in the perivascular spaces and invading blood vessel walls. The olfactory bulbs and spinal cord are usually spared.

Clinical Manifestations.

The incubation of *Naegleria* infection may be as short as 2 days or as long as 15 days. Symptoms have an acute onset and are rapidly progressive. There is a sudden onset of severe headache, fever, nausea, and vomiting; signs of meningitis; and then encephalitis. Most cases end in death within 1 wk of onset of symptoms.

Granulomatous amebic meningoencephalitis may occur weeks to months after acquiring the organism. The presenting signs and symptoms are often those of single or multiple CNS space-occupying lesions; they include hemiparesis, personality changes, seizures, and drowsiness. Altered mental status is often a prominent symptom. Headache and fever occur only sporadically, but stiff neck is seen in a majority of cases. Palsies of the cranial nerves may be present. There is also one report of acute hydrocephalus and fever with *Balamuthia*. Results of neuroimaging studies of the brain usually demonstrate multiple low-density lesions resembling infarcts.

Diagnosis.

The CSF in *Naegleria* infection may mimic that of herpes simplex encephalitis early in the disease and, later, of acute bacterial meningitis, with a neutrophilic pleocytosis, elevated protein level, and low glucose level. The amebas, which may be motile, may be seen on a wet mount of the CSF but are often mistaken for lymphocytes. A hanging drop examination of CSF and a strong clinical suspicion early in the course of disease affords the best chance for early treatment and cure. *Naegleria* can be grown on agar enriched with gram-negative bacteria, on which they feed.

In granulomatous meningoencephalitis, findings of examination of the CSF resemble those of aseptic meningitis. The isolation and identification of *Acanthamoeba* from the CNS are the best methods of diagnosis. Brain tissue and CSF may be cultured for *Acanthamoeba* using the same agar used for growing *Naegleria*, but *Balamuthia* must be grown on mammalian cell cultures. Pediatric cases of *Balamuthia* meningoencephalitis have been diagnosed post mortem or by brain biopsy ante mortem. Immunofluorescence staining of brain tissue can differentiate between *Acanthamoeba* and *Balamuthia.*

Treatment.

Naegleria infection is nearly always fatal, and early recognition and early treatment are crucial to successful therapy. There have only been six treatment survivors, five of whom apparently recovered fully. *Naegleria* infections have been successfully treated with regimens of amphotericin B, rifampin, and chloramphenicol; amphotericin B, oral rifampin, and oral ketoconazole; and amphotericin alone. The duration of treatment is uncertain.

Trophozoites and cysts from *Acanthamoeba* keratitis are usually susceptible in vitro to chlorhexidine, polyhexamethyl biguanide (PHMB), propamidine, pentamidine, diminazene, and neomycin, and especially to combinations of these drugs.

There is no satisfactory treatment for granulomatous amebic meningoencephalitis. Strains of *Acanthamoeba* isolated from fatal cases are usually susceptible in vitro to pentamidine, ketoconazole, flucytosine, and less so to amphotericin B. One patient has been successfully treated with sulfadiazine and fluconazole and another with intravenous pentamidine, topical chlorhexidine, and 2% ketoconazole cream, followed by oral itraconazole. Limited success has been demonstrated in *Balamuthia* infection with systemic azole therapy combined with flucytosine. Corticosteroids appear to have a detrimental effect, with rapid progression of disease, and should be avoided.

Chapter 257 - Amebiasis

Chandy C. John
Robert A. Salata

Human infection with *Entamoeba* is prevalent worldwide; endemic foci are particularly common in the tropics, especially in areas with low socioeconomic and sanitary standards. *Entamoeba* parasitizes the lumen of the gastrointestinal tract and causes few or no symptoms or sequelae in most infected subjects. In a small proportion of individuals the organisms invade the intestinal mucosa or may disseminate to other organs, especially the liver.

Etiology.

There are two morphologically identical but genetically distinct species of *Entamoeba* that commonly infect humans. *Entamoeba dispar,* the more prevalent species, is associated only with an asymptomatic carrier state. *Entamoeba histolytica,* the pathogenic species, can become invasive, causing symptomatic disease. Five other species of nonpathogenic *Entamoeba* infrequently colonize the human gastrointestinal tract: *E. coli, E. hartmanni, E. gingivalis, E. moshkovskii,* and *E. polecki.*

Infection is established by ingestion of parasite cysts, measuring 10–18?µm, that contain four nuclei. Cysts are resistant to environmental conditions such as low temperature and the concentrations of chlorine commonly used in water purification; the parasite can be killed by heating to 55°C. On ingestion, the cyst, which is resistant to gastric acidity and digestive enzymes, excysts in the small intestine to form eight trophozoites. These are large, actively motile organisms that colonize the lumen of

the large intestine and may invade its mucosal lining under conditions that are currently unknown. Infection is not transmitted by trophozoites because of their rapid degeneration outside the body or in the low pH environment of normal gastric contents. Trophozoites have an average diameter of 25?µm, with a single spherical nucleus containing fine peripheral chromatin and a central nucleolus. The endoplasm also contains vacuoles, where, in cases of invasive amebiasis, erythrocytes may be seen.

Epidemiology.

The regional prevalence of amebic infections worldwide varies from 5–81%, with the highest frequency in the tropics. Humans are the major reservoir. It is estimated that 10%, approximately 480 million people, of the population worldwide is infected with *E. dispar* or *E. histolytica.* This infection is associated with 50 million cases of symptomatic disease and an annual mortality of 40,000–110,000 deaths; amebiasis is the third leading parasitic cause of death worldwide. *E. dispar* is 10-fold more common than is *E. histolytica.* Symptomatic disease occurs in about 10% of individuals with *E. histolytica* infection. Therefore, invasive disease occurs in approximately 1% of persons determined to be infected with *Entamoeba* by light microscopy. Dissemination of the parasites to internal organs such as the liver occurs in an even smaller fraction of infected individuals and is less common in children than in adults.

Although highly endemic in Africa, Latin America, India, and Southeast Asia, amebiasis is not exclusively limited to the tropics. In the United States, amebiasis has been estimated to occur with a prevalence of 1–4% in certain high-risk groups, including chronically institutionalized persons, mentally retarded children, promiscuous homosexual males, emigrants from and travelers to endemic areas, migrant workers, and individuals in lower socioeconomic groups. Most children infected with *Entamoeba* fall into these risk groups.

Food or drink contaminated with *Entamoeba* cysts and direct fecal-oral contact are the most common means of infection. Untreated water and human feces used as fertilizer are important sources of infection. Food handlers carrying amebic cysts may, therefore, play a role in spreading the infection. Direct contact with infected feces also may be responsible for person-to-person transmission.

Pathogenesis.

Trophozoites, which are responsible for tissue invasion and destruction, attach to the colonic mucosa by a galactose-specific lectin receptor. This receptor is also thought to be responsible for resistance to complement-mediated lysis. Once attached to the colonic mucosa, amebas release a cysteine-rich proteinase that allows for penetration through the epithelial layer. *E. histolytica* trophozoites require direct contact with target cells to cause cell death. Host cells are destroyed by trophozoite release of spore-forming peptides, phospholipases, and hemolysins. Once *E. histolytica* trophozoites invade the intestinal mucosa, they produce tissue destruction (ulcers) with little local inflammatory response because of the cytolytic capacity of the organism. The organisms multiply and spread laterally underneath the intestinal epithelium to produce characteristic flask-shaped ulcers. These lesions are commonly seen in the cecum, transverse colon, and sigmoid colon. Amebae may produce similar lytic lesions if they reach the liver; these lesions are commonly called abscesses, although they contain no granulocytes. The disparity between the extent of tissue destruction by amebae and the absence of a local host inflammatory response in the presence of systemic humoral (antibody) and cell-mediated

responses remains a major scientific puzzle.

Clinical Manifestations.

Clinical presentations range from asymptomatic cyst passage to amebic colitis, amebic dysentery, ameboma, and extraintestinal disease. To date, *E. dispar* has not been associated with symptomatic disease. *E. histolytica* infection is asymptomatic in 90% of persons, but it has the potential to become invasive and thus should be treated. Severe disease is more common in young children, pregnant women, malnourished individuals, and person using corticosteroids.

Extraintestinal disease usually involves only the liver, but rare extraintestinal manifestations include amebic brain abscess, pleuropulmonary disease, and ulcerative skin and genitourinary lesions.

INTESTINAL AMEBIASIS.

Intestinal amebiasis may occur within 2 wk of infection or be delayed for months. The onset is usually gradual with colicky abdominal pains and frequent bowel movements (6–8/day). Diarrhea is frequently associated with tenesmus. Stools are blood stained and contain a fair amount of mucus with few leukocytes. Generalized constitutional symptoms and signs are characteristically absent, with fever documented in only one third of patients. Amebic colitis affects all age groups, but its incidence is strikingly high in children 1–5 yr of age. Severe amebic colitis in infants and young children tends to be rapidly progressive with frequent extraintestinal involvement and high mortality rates, particularly in tropical countries. Occasionally, amebic dysentery is associated with sudden onset of fever, chills, and severe diarrhea, which may result in dehydration and electrolyte disturbances. In a few patients complications such as ameboma, toxic megacolon, extraintestinal extension, or local perforation and peritonitis may occur.

Uncommonly, a chronic form of amebic colitis develops, which can mimic inflammatory bowel disease with bouts of abdominal pain and bloody diarrhea, often recurring over several years. An **ameboma** is a nodular focus of proliferative inflammation sometimes developing in chronic amebiasis, usually in the wall of the colon. Chronic amebiasis should be excluded before initiating corticosteroid treatment for inflammatory bowel disease.

HEPATIC AMEBIASIS.

Hepatic amebiasis is a very serious manifestation of disseminated infection. Although diffuse liver enlargement has been associated with intestinal amebiasis, liver abscess occurs in less than 1% of infected individuals and may appear in patients with no clear history of intestinal disease. In children, fever is the hallmark of amebic liver abscess and is frequently associated with abdominal pain, distention, and enlargement and tenderness of the liver. Changes at the base of the right lung, such as elevation of the diaphragm and atelectasis or effusion, may also occur. Laboratory examination findings are a slight leukocytosis, moderate anemia, high erythrocyte sedimentation rate, and nonspecific elevations of hepatic enzyme (particularly alkaline phosphatase) level. Stool examination for amebae yields negative results in more than 50% of patients with documented amebic liver abscess. In most cases, CT, MRI, or isotope scans can localize and delineate the size of the abscess cavity. Most patients have a single cavity in the right hepatic lobe, although results of recent studies employing CT have shown an increased rate of multiple abscesses and left lobe involvement. Amebic liver abscess may be associated with rupture into the peritoneum or thorax or through the skin when diagnosis and therapy are delayed.

Diagnosis.

Diagnosis is based on detecting the organisms in stool samples, sigmoidoscopically obtained smears, tissue biopsy samples, or, rarely, aspirates of a liver abscess. Examination of three fresh stool samples by experienced laboratory personnel has a sensitivity of 90% for detecting *Entamoeba.* Fresh stool samples should be examined within 30?min of passage and screened for motile trophozoites containing erythrocytes. Whenever amebiasis is suspected, an additional stool sample should be preserved in polyvinyl alcohol for further examination. Endoscopy and biopsies of suspicious areas should be performed when stool sample results are negative and the index of suspicion for amebiasis remains high. Unfortunately, unless phagocytized erythrocytes are seen, microscopy findings do not distinguish between *E. histolytica* and *E. dispar.* Patients with invasive amebic colitis have positive test results for fecal occult blood.

Various serum antiamebic antibody tests are available. Serologic results are positive in 95% of patients with symptomatic disease of more than 7 days and in most asymptomatic carriers of pathogenic strains of *Entamoeba*. *E. dispar* does not elicit a humoral response. The most sensitive serologic test, indirect hemagglutination, yields a positive result years after invasive infection. Antigen detection in stool or serum can establish a diagnosis while also distinguishing *E. dispar* from *E. histolytica.* Antigen detection tests are not yet routinely available.

Treatment.

Two types of drugs are used to treat infection with *E. histolytica.* The luminal amebicides, such as iodoquinol, paromomycin, and diloxanide furoate, are primarily effective in the gut lumen. Metronidazole or other nitroimidazoles, chloroquine, and dehydroemetine are effective in the treatment of invasive amebiasis. All individuals with *E. histolytica* trophozoites or cysts in their stools, whether symptomatic or not, should be treated. The recommended regimen for treating asymptomatic cyst carriers is iodoquinol (30–40?mg/kg/24?hr divided tid PO for 20 days; maximum: 650?mg/dose). Paromomycin (25–35?mg/kg/24?hr divided tid PO for 7 days), a nonabsorbable aminoglycoside, is an alternative. Diloxanide furoate is only available through the Centers for Disease Control and Prevention (CDC). Toxicity is rare, but the drug should not be used in children younger than 2 yr of age.

Invasive amebiasis of the intestine, liver, or other organs requires the use of metronidazole (30–50?mg/kg/24?hr divided tid PO for 10 days; maximum: 500–750?mg/dose), a tissue amebicidal drug. Two related nitroimidazoles, tinidazole and ornidazole, are available and have been used outside the United States.

Adverse effects of metronidazole include nausea, abdominal discomfort, and metallic taste; these are uncommon and disappear after completion of therapy. Metronidazole is also a luminal amebicide but is less effective for this purpose and should be followed by a luminal agent. Metronidazole-resistant *E. histolytica* has not been reported. Nevertheless, for fulminant cases, some experts suggest adding dehydroemetine (1?mg/kg/24?hr subcutaneously or IM, never IV), which is available only through the CDC. Patients should be hospitalized when dehydroemetine is given, and the drug should be discontinued if tachycardia, T-wave depression, arrhythmias, or proteinuria develops. Chloroquine, which concentrates in the liver, may be useful in the treatment of amebic hepatic abscess. Aspiration of large lesions or left lobe abscesses may be necessary if rupture is imminent or if the patient shows a poor clinical response 4–6 days after administration of amebicidal drugs.

Stool examination should be repeated every 2 wk until the result is negative after completion of antiamebic therapy to confirm cure.

Prognosis.

Most infections evolve to either an asymptomatic carrier state or eradication. Death occurs in about 5% of persons having extraintestinal infection.

Prevention.

Control of amebiasis can be achieved by exercising proper sanitary measures and avoiding fecal-oral contact. Regular examination of food handlers and thorough investigation of diarrheal episodes may identify the source of infection in some communities. No prophylactic drug or vaccine is available for amebiasis.

Chapter 258 - Giardiasis and Balantidiasis

Larry K. Pickering

258.1 *Giardia lamblia*

Giardia lamblia (also referred to as *G. intestinalis* and *G. duodenalis*) is a flagellated protozoan that infects the duodenum and small intestine. Infection results in a wide variety of clinical manifestations, ranging from asymptomatic colonization to acute or chronic diarrhea and malabsorption. Infection is more prevalent in children than in adults. *Giardia* organisms are endemic in areas of the world with poor levels of sanitation and also are an important cause of morbidity in developed countries, where they are associated with urban child-care centers, residential institutions for the mentally delayed, and waterborne and foodborne outbreaks. *Giardia* is a particularly significant pathogen in people with malnutrition, certain immunodeficiencies, and cystic fibrosis.

Etiology.

The life cycle of *Giardia* is composed of two stages: trophozoites and cysts. *Giardia* infects humans after ingestion of as few as 10–100 cysts. Ingested cysts, which measure 8–10?µm, each produce two trophozoites in the duodenum. After excystation, trophozoites colonize the lumen of the duodenum and proximal jejunum, where they attach to the brush border of the intestinal epithelial cells and multiply by binary fission. The body of the trophozoite is teardrop shaped, measuring 10–20?µm in length and 5–15?µm in width. *Giardia* trophozoites contain two oval nuclei anteriorly, a large ventral disk, a curved median body posteriorly, and four pair of flagella. As detached trophozoites pass down the intestinal tract, they encyst to form oval cysts that contain four nuclei. Cysts are passed in stools of infected individuals and may remain viable in water for as long as 2 mo. Their viability often is not affected by the usual concentrations of chlorine used to purify water for drinking.

Giardia strains that infect humans are diverse biologically, as shown by differences in antigens, restriction endonuclease patterns, DNA fingerprinting, isoenzyme patterns, and pulsed-field gel electrophoresis. Differences in clinical manifestations and antimicrobial susceptibility patterns of various strains remain unknown.

Epidemiology.

Giardia occurs worldwide and is the most common intestinal parasite identified in public health laboratories in the United States. *Giardia* infection usually occurs sporadically but is a frequently identified etiologic agent of outbreaks associated with drinking water. The age-specific prevalence of giardiasis is high during childhood and begins to decline after adolescence. The asymptomatic carrier rate of *G. lamblia* in the United States is estimated to be 3–7%, and as high as 20% in southern regions and in children younger than 36 mo of age attending child-care centers. Asymptomatic carriage may persist for several months.

Transmission of *Giardia* is common in certain high-risk groups, including children and employees in child-care centers, consumers of contaminated water, travelers to certain areas of the world, male homosexuals, and persons exposed to certain animals. The major reservoir and vehicle for spread of *Giardia* appears to be water contaminated with *Giardia* cysts, but foodborne transmission occurs. The seasonal peak in age-specific case reports coincides with the summer recreational water season and might be a result of the extensive use of communal swimming venues by young children, the low infectious dose, and the extended periods of cyst shedding that can occur. In addition, *Giardia* cysts are relatively resistant to chlorination and to ultraviolet light irradiation. Boiling is effective for inactivating cysts.

Person-to-person spread also occurs, particularly in areas of low hygiene standards, frequent fecal-oral contact, and crowding. Individual susceptibility, lack of toilet training, crowding, and fecal contamination of the environment all predispose to transmission of enteropathogens, including *Giardia*, in child-care centers. Child-care centers play an important role in transmission of urban giardiasis, with secondary attack rates in families as high as 17–30%. Children in child-care centers may pass cysts for several months.

Humoral immunodeficiencies including common variable hypogammaglobulinemia and X-linked agammaglobulinemia predispose humans to chronic symptomatic *Giardia* infection, suggesting the importance of humoral immunity in controlling giardiasis. There is no convincing evidence that patients with acquired immunodeficiency syndrome (AIDS) or selective immunoglobulin A (IgA) deficiency have more severe or prolonged disease. There is a higher incidence of *Giardia* infection in patients with cystic fibrosis, probably owing to local factors such as the increased amount of mucus, which may protect the organism against host factors in the duodenum. Human milk contains glycoconjugates and secretory IgA antibodies that may provide protection to nursing infants.

Clinical Manifestations.

The incubation period of *Giardia* infection usually is 1–2 wk but may be longer. A broad spectrum of clinical manifestations occurs, depending on the interaction between *G. lamblia* and the host. Children who are exposed to *G. lamblia* may

experience asymptomatic excretion of the organism, acute infectious diarrhea, or chronic diarrhea with persistent gastrointestinal tract signs and symptoms, including failure to thrive. Most infections in both children and adults are asymptomatic. There usually is no extraintestinal spread, but occasionally trophozoites may migrate into bile or pancreatic ducts.

Symptomatic infections occur more frequently in children than in adults. Most symptomatic patients usually have a limited period of acute diarrheal disease with or without low-grade fever, nausea, and anorexia; in a small proportion an intermittent or more protracted course characterized by diarrhea, abdominal distention and cramps, bloating, malaise, flatulence, nausea, anorexia, and weight loss develops (Table 258–1). Initially, stools may be profuse and watery and later become greasy and foul smelling and may float. Stools do not contain blood, mucus, or fecal leukocytes. Varying degrees of malabsorption may occur. Abnormal stool patterns may alternate with periods of constipation and normal bowel movements. Malabsorption of sugars, fats, and fat-soluble vitamins has been well documented and may be responsible for substantial weight loss.

Diagnosis.

Giardiasis should be considered in young children in child care or in any person who has had contact with an index case or a history of recent travel to an endemic area who has persistent diarrhea, intermittent diarrhea and constipation,

TABLE 258.1-1 -- **Clinical Signs and Symptoms of Giardiasis**

Symptom	Frequency (%)
Diarrhea	64–100
Malaise, weakness	72–97
Abdominal distention	42–97
Flatulence	35–97
Abdominal cramps	44–81
Nausea	14–79
Foul-smelling, greasy stools	15–79
Anorexia	41–73
Weight loss	53–73
Vomiting	14–35
Fever	0–28
Constipation	0–27

malabsorption, crampy abdominal pain and bloating, or failure to thrive or weight loss.

A definitive diagnosis of giardiasis is established by documentation of trophozoites, cysts, or *Giardia* antigens in stool specimens or duodenal fluid. Several types of specimens from the gastrointestinal tract can be used to diagnose *Giardia* infection. For both trophozoites and cysts of *Giardia* organisms, identification can be made on direct smears of stool or after concentration of stool specimens. Stool specimens should be examined within 1?hr of passage or should be preserved in vials containing polyvinyl alcohol (PVA) or 10% formalin, both of which preserve parasite morphologic characteristics. Trophozoites may be present in unformed stools as a result of rapid bowel transit; they are not stable outside the gastrointestinal tract. Cysts are stable outside the gastrointestinal tract and are the infectious form.

In patients in whom the diagnosis is suspected but in whom examination of stool specimens for *Giardia* yields a negative result, aspiration or biopsy of the duodenum or upper jejunum should be performed. In a fresh specimen, trophozoites usually can be visualized by direct wet mount. An alternate method of directly obtaining duodenal fluid is the commercially available Entero-Test (Hedeco Corp, Mountain View, CA). The biopsy can be used to make touch preparations and tissue sections for identification of *Giardia* and other enteric pathogens, as well as to visualize changes in histologic features. Biopsy of the small intestine should be considered in patients with characteristic clinical symptoms, negative stool and duodenal fluid specimen findings, and one of the following: abnormal radiographic findings, such as edema and segmentation in the small intestine; abnormal lactose tolerance test result; absent secretory IgA level; hypogammaglobulinemia; or achlorhydria.

Medications, including antimicrobial agents, antacids, antidiarrheals, and enema and laxative preparations, can interfere with identification of the organism by altering their morphologic characteristics or by causing a temporary disappearance of parasites from stool specimens. Patients should not take these compounds for 48–72?hr before collection of stool for identification of *Giardia.* Contrast material such as barium also will mask the presence of parasites.

Appropriately conducted direct examination of stool will establish the diagnosis in up to 70% of patients by a single examination, 85% by examination of a second stool specimen, and more than 90% by examination of three specimens. Comparison of stool examination results with small bowel aspiration results in patients with diarrhea revealed that parasites were detected in 50% of stools of patients in whom a small bowel focus of infection was documented by aspiration. Laboratories can reduce reagent and personnel costs by pooling specimens submitted for detection of *Giardia* before evaluation by either microscopy or by enzyme immunoassay (EIA).

Efforts to improve diagnostic testing include the use of polyclonal antisera or monoclonal antibodies against *Giardia* organism–specific antigens in EIA or immunofluorescent assays. Polymerase chain reaction and gene probe–based detection systems specific for *Giardia* have been used in environmental monitoring.

Radiographic contrast studies of the small intestine may show nonspecific findings such as irregular thickening of the mucosal folds. Blood cell counts usually are normal. Giardiasis is not associated with eosinophilia.

Treatment.

Children with acute diarrhea in whom *Giardia* organisms are identified should receive therapy. In addition, children who manifest failure to thrive or exhibit malabsorption or gastrointestinal tract symptoms such as chronic diarrhea should be treated.

Asymptomatic excreters generally are not treated except in specific instances such as in outbreak control, for prevention

TABLE 258.1-2 -- Oral Antimicrobial Therapy for Giardiasis

Antiprotozoal Agent	Pediatric Dose	Adult Dose
Albendazole (Albenza)	400?mg once a day for 5 days PO	400?mg once a day PO for 5 days
Furazolidone (Furoxone)	6?mg/kg/24?hr divided qid PO for 10 days (maximum: 400?mg/24?hr)	100?mg qid PO for 10 days
Metronidazole (Flagyl)	15?mg/kg/24?hr divided tid PO for 5 days (maximum: 750?mg/24?hr)	250?mg tid PO for 5 days
Paromomycin	Not recommended	30?mg/kg/24?hr tid PO for 7 days (maximum: 1500?mg/24?hr)
Quinacrine* (Atabrine)	6?mg/kg/24?hr divided tid PO for 5 days (maximum: 300?mg/24?hr)	100?mg tid PO for 7 days
Tinidazole	50?mg/kg once (maximum: 2 g). Not available in the United States	2?gm PO once. Not available in the United States

**Can be compounded by Medical Center Pharmacy in New Haven, CT (203-785-6818) or Panorama Compounding Pharmacy in Van Nuys, CA (800-247-9767).*

of household transmission by toddlers to pregnant women and patients with hypogammaglobulinemia or cystic fibrosis, and in situations requiring oral antibiotic treatment where *Giardia* may have produced malabsorption of the antibiotic.

There are several drugs available in the United States that are effective in the treatment of patients with giardiasis, including albendazole, furazolidone, metronidazole, paromomycin, and quinacrine (Table 258–2). Tinidazole is used in other countries as single-dose therapy but is not available in the United States.

Metronidazole is the treatment most often prescribed in the United States for adults. Furazolidone is less effective than metronidazole but is often prescribed in children because it is available in liquid form. Furazolidone is the only drug approved by the U.S. Food and Drug Administration for treatment of giardiasis. Quinacrine is effective and inexpensive but is not available from any U.S. manufacturer. Albendazole appears to be as effective as metronidazole with fewer adverse effects among children 2–12 yr of age and is effective against many helminths, making it useful for treatment when multiple intestinal parasites are identified or suspected. Paromomycin, a nonabsorbable aminoglycoside, is less effective than other agents but is recommended for treatment of pregnant women with giardiasis because of potential teratogenic effects of other agents. A combination of metronidazole and quinacrine has been used to treat refractory cases.

Prognosis.

Symptoms recur in some patients, in whom reinfection cannot be documented and in whom an immune deficiency such as an immunoglobulin abnormality is not present, despite use of appropriate therapy. Several studies have demonstrated that variability in antimicrobial susceptibility exists among strains of *Giardia,* and in some instances resistant strains have been demonstrated. Combined therapy may benefit patients in whom infection persists after single-drug therapy, assuming reinfection has not occurred and the medication was taken as prescribed.

Prevention.

Infected persons and persons at risk should practice strict handwashing after any contact with feces. This is especially important for caregivers of diapered infants in child-care centers, where diarrhea is common and *Giardia* organism carriage rates are high.

Methods to purify public water supplies adequately include chlorination, sedimentation, and filtration. Inactivation of *Giardia* cysts by chlorine requires the coordination of multiple variables such as chlorine concentration, water pH, turbidity, temperature, and contact time. These variables cannot be appropriately controlled in all municipalities and are difficult to control in swimming pools. People, especially children in diapers, should avoid swimming if they have diarrhea. People should avoid swallowing recreational water and drinking untreated water from shallow wells, lakes, springs, ponds, streams and rivers.

Travelers to endemic areas are advised to avoid uncooked foods that might have been grown, washed, or prepared with water that was potentially contaminated. Purification of drinking water can be achieved by a filter with a pore size of 1?µm or less or one that has been National Sanitation Foundation-rated for cyst removal, or by brisk boiling of water for at least 1?min. Treatment of water with chlorine or iodine is somewhat less effective but may be used as an alternate method when boiling or filtration is not possible.

258.2 Balantidiasis

Balantidium coli is a ciliated protozoan and is the largest protozoan that parasitizes humans. Both trophozoites and cysts may be identified in feces. Disease caused by

this organism is uncommon in the United States and generally is reported where there is a close association of humans with pigs, which are the natural hosts of the organism. Because the organism infects the large intestine, symptoms are consistent with large bowel disease, similar to those associated with amebiasis and trichuriasis, and include nausea, vomiting, lower abdominal pain, tenesmus, and bloody diarrhea. Symptoms associated with chronic infection include abdominal cramps, watery diarrhea with mucus, occasionally bloody diarrhea, and colonic ulcers similar to those associated with *Entamoeba histolytica*. Extraintestinal spread of *B. coli* does not occur, and most infections are asymptomatic.

Diagnosis using direct saline mounts is established by identification of trophozoites (50–100?µm long) or spherical or oval cysts (50–70?µm in diameter) in stool specimens. Trophozoites usually are more numerous than cysts. The recommended treatment regimen is metronidazole (45?mg/kg/24?hr divided tid PO; maximum: 750?mg/dose) for 5 days, or tetracycline (40?mg/kg/ 24?hr divided qid PO; maximum: 500?mg/dose) for 10 days for persons 8 yr of age or older; an alternative is iodoquinol (40?mg/kg/24?hr divided tid PO; maximum: 650?mg/dose) for 20 days. Prevention of contamination of the environment by pig feces is the important means for control.

Chapter 259 - Spore-Forming Intestinal Protozoa

Patricia M. Flynn

The spore-forming intestinal protozoa—*Cryptosporidium, Isospora, Cyclospora,* and microsporidia—have become increasingly important intestinal pathogens in both immunocompetent and immunocompromised hosts during the past decade. The severity of illness in HIV-infected patients and those with AIDS and improved diagnostic capabilities have helped elucidate the epidemiologic characteristics and clinical manifestations of these organisms. *Cryptosporidium, Isospora,* and *Cyclospora* are coccidian parasites that predominantly infect the epithelial cells lining the digestive tract. Microsporidia are ubiquitous, obligate intracellular protozoa that infect many other organ systems in addition to the gastrointestinal tract and cause a broader spectrum of disease.

CRYPTOSPORIDIUM

Initially, *Cryptosporidium* was thought to be pathogenic almost exclusively in immunocompromised persons. It is now recognized to be a leading protozoal cause of diarrhea in children worldwide and is a common cause of outbreaks in child-care centers.

Etiology.

Infection with *Cryptosporidium parvum,* the cause of cryptosporidiosis in humans, is initiated by ingestion of infectious oocysts. The oocyst releases four sporozoites that invade enterocytes, primarily in the small intestine. The infection progresses through two stages: the asexual, which allows autoinfection at the luminal surface of the epithelium, and the sexual, which results in production of oocysts that are shed in the stools. The cysts are immediately infectious to other hosts or can reinfect the same host. Ingestion of very few cysts is required to produce infection, even in immunocompetent hosts.

Epidemiology.

Cryptosporidiosis is associated with diarrheal illness worldwide and is more prevalent in developing countries and in children younger than 2 yr of age. It has been implicated as an etiologic agent of persistent diarrhea in the developing world and as a cause of significant morbidity and mortality from malnutrition, including permanent effects on growth.

Transmission of *Cryptosporidium* to humans can occur by close association with infected animals, via person-to-person transmission, or from environmentally contaminated water. Although zoonotic transmission, especially from cows, occurs in persons in close association with animals, person-to-person transmission is probably responsible for cryptosporidiosis outbreaks within hospitals and child-care centers, where rates as high as 67% have been reported. Recommendations to prevent outbreaks in child-care centers include strict handwashing, use of protective clothes or diapers capable of retaining liquid diarrhea, and separation of diapering and food handling areas and responsibilities.

Outbreaks of cryptosporidial infection have been associated with contaminated community water supplies and recreational waters in several states in the United States and in Great Britain. Wastewater, in the form of raw sewage, and runoff from dairies and grazing lands can contaminate both drinking and recreational water sources. It is estimated that *Cryptosporidium* oocysts are present in 65–97% of the surface water in the United States. The organism's small size (4–6?µm in diameter), resistance to chlorination, and ability to survive for long periods outside a host create problems in public water supplies. A waterborne outbreak in 1993 in Milwaukee, Wisconsin, caused more than 400,000 cases of diarrhea.

Clinical Manifestations.

The incubation period is 2–14 days. Infection with *Cryptosporidium* is associated with profuse, watery, nonbloody diarrhea that can be accompanied by diffuse crampy abdominal pain, nausea, vomiting, and anorexia. Although less common in adults, vomiting occurs in more than 80% of children with cryptosporidiosis. Nonspecific symptoms such as myalgia, weakness, and headache also may occur. Fever occurs in 30–50% of cases. Malabsorption, lactose intolerance, dehydration, weight loss, and malnutrition often occur in severe cases.

In immunocompetent hosts, the disease is usually self-limiting, although diarrhea may persist for several weeks and oocyst shedding may persist many weeks after symptoms resolve. Chronic diarrhea is common in individuals with immunodeficiency, such as congenital hypogammaglobulinemia or HIV infection. Symptoms and oocyst shedding can continue indefinitely and may lead to severe malnutrition, wasting, anorexia, and even death.

Cryptosporidiosis in immunocompromised hosts is often associated with biliary tract disease, characterized by fever, right upper quadrant pain, nausea, vomiting, and diarrhea. It also has been associated with pancreatitis. Respiratory tract disease, with symptoms of cough, shortness of breath, wheezing, croup, and hoarseness, is very rare.

Diagnosis.

Infection is best diagnosed by identifying oocysts in feces or other body fluids or

tissues. In stool, they appear as small, spherical bodies (2–6?µm) and stain red when using modified acid-fast staining. Staining for *Cryptosporidium* should be specifically requested so that appropriate concentration and staining techniques can be employed. Because *Cryptosporidium* does not invade below the epithelial layer of the mucosa, fecal leukocytes are not found in stool specimens.

Because oocyst shedding in feces can be intermittent, several fecal specimens (at least three for an immunocompetent host) should be collected for microscopic examination. In addition to the modified acid-fast staining procedure, enzyme immunoassay, indirect immunofluorescence, and polymerase chain reaction testing are available. Serologic diagnosis is not helpful in acute cryptosporidiosis.

In tissue sections, *Cryptosporidium* organisms can be found along the microvillus region of the epithelia that line the gastrointestinal tract. The highest concentration usually is detected in the jejunum. Histologic section results reveal villus atrophy and blunting, epithelial flattening, and inflammation of the lamina propria.

Treatment.

Because the diarrheal illness due to cryptosporidiosis is self-limited in immunocompetent patients, no specific antimicrobial therapy is required. Treatment should focus on supportive care, consisting of rehydration orally, or, if fluid losses are severe, intravenously.

Immunocompromised patients with severe cryptosporidial enteritis have been treated with a variety of antibiotics, none of which has been consistently effective. Nitazoxanide (100?mg bid PO for 3 days) was effective in children in Egypt; it is only available on an investigative basis in the United States. Combination therapy with paromomycin (1?g bid PO) and azithromycin (600?mg/day PO) for 4 wk followed by paromomycin monotherapy for 8 wk has also been used in adult patients with AIDS. Treatment with orally administered human serum immunoglobulin or bovine colostrum has been successful in several anecdotal reports.

ISOSPORA

Like *Cryptosporidium, Isospora belli* has been implicated as a cause of diarrhea in institutional outbreaks and in travelers and has also been linked with contaminated water and food. *Isospora* appears to be more common in tropical and subtropical climates and in developing areas, including South America, Africa, and Southeast Asia. *Isospora* has not been associated with animal contact. It is also an infrequent cause of diarrhea in patients with AIDS in the United States but may infect up to 15% of AIDS patients in Haiti.

The life cycle and pathogenesis of infection with *Isospora* species are similar to those of *Cryptosporidium* organisms except that oocysts excreted in the stool are not immediately infectious and must undergo further maturation below 37℃. Histologic appearance of gastrointestinal epithelium reveals blunting and atrophy of the villi, acute and chronic inflammation, and crypt hyperplasia.

The clinical manifestations are indistinguishable from those of cryptosporidiosis, although fever may be a more common finding. Eosinophilia, not found with other enteric protozoan infections, may be present. The diagnosis is established by detecting the oval, 22–33?µm long by 10–19?µm wide, oocysts by using modified acid-fast staining of the stool. Each oocyst contains two sporocysts with four sporozoites in each. Fecal leukocytes are not detected.

Unlike cryptosporidiosis, isosporiasis responds promptly to treatment with oral trimethoprim-sulfamethoxazole (TMP-SMZ) (5?mg TMP, 25?mg SMZ/kg/dose; maximum: 160?mg TMP, 800?mg SMZ/dose qid for 10 days, then bid for 3 wk). In patients with AIDS, relapses are common and often necessitate maintenance therapy. Ciprofloxacin, or a regimen of pyrimethamine alone or with folinic acid, is effective in patients intolerant of sulfonamide drugs.

CYCLOSPORA

Cyclospora cayetanensis is a coccidian parasite similar to but larger than *Cryptosporidium parvum.* Cyclosporiasis is endemic in Nepal, Peru, and Haiti but may be found throughout the world. The organism infects both immunocompromised and immunocompetent individuals and is more common in children younger than 18 mo of age. The pathogenesis and pathologic findings of cyclosporiasis are similar to those of isosporiasis. Asymptomatic carriage of the organism has been found, but travelers who harbor the organism almost always have diarrhea. Outbreaks of cyclosporiasis have been linked with contaminated food and water. After fecal excretion, the oocysts must sporulate to become infectious. This finding explains the lack of person-to-person transmission.

The clinical manifestations of cyclosporiasis are similar to those of cryptosporidiosis and isosporiasis and follow an incubation period of approximately 7 days. Moderate *Cyclospora* illness is characterized by a median of 6 stools/day with a median duration of 10 days (range, 3–25 days). The duration of diarrhea in immunocompetent persons is characteristically longer in cyclosporiasis than in the other intestinal protozoan illnesses. Associated symptoms frequently include fatigue; abdominal bloating or gas; abdominal cramps or pain; nausea; muscle, joint, or body aches; fever; chills; headache; and weight loss. Vomiting may occur. Bloody stools are uncommon. Biliary disease has been reported.

The diagnosis is established by identification of oocysts in the stool. Oocysts are wrinkled spheres, measure 8–10?µm in diameter, and resemble large *Cryptosporidium* organisms. Each oocyst contains two sporocysts, each with two sporozoites. The organisms can be seen by using modified acid-fast staining but stain less consistently than *Cryptosporidium*. They can also be detected with phenosafranin stain and by autofluorescence using strong green or intense blue under ultraviolet (UV) epifluorescence. Fecal leukocytes are not present.

The treatment of choice for cyclosporiasis, as for isosporiasis, is trimethoprim-sulfamethoxazole (5?mg TMP, 25?mg SMZ/kg/ dose bid PO for 7 days; maximum: 160?mg TMP, 800?mg SMZ/dose). Ciprofloxacin is effective in patients

intolerant of sulfonamide drugs.

MICROSPORIDIA

Microsporidia are ubiquitous and infect most animal groups, including humans. At least seven genera and unclassified organisms of the order Microsporidia have been linked with human disease in both immunocompetent and immunocompromised hosts. The microsporidian organisms best associated with gastrointestinal disease are *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis.*

Little is known about the epidemiologic characteristics of these organisms, but they are likely similar to that of the other spore-forming intestinal protozoa. There have been recent reports of waterborne outbreaks. Unlike *Cryptosporidium* and the other protozoa, spores of microsporidia inject their contents into the host cell to establish infection. Intracellular division produces new spores that can spread to nearby cells, disseminate to other host tissues, or be passed into the environment via feces. Spores also have been detected in urine and respiratory epithelium, suggesting that some body fluids may also be infectious. Once in the environment, microsporidial spores remain infectious for up to 4 mo.

Microsporidial intestinal infection has been almost exclusively reported in patients with AIDS, but this finding may be due to the difficulty in diagnosing the infection. Microsporidia-associated diarrhea is intermittent, copious, watery, and nonbloody. Abdominal cramping and weight loss may be present; fever is unusual. Disseminated disease, involving liver, kidney, bladder, biliary tract, lung, bone, and sinuses, has been reported.

Microsporidia stain with hematoxylin-eosin, Giemsa, Gram, periodic acid–Schiff, and acid-fast stains but are often overlooked because of their small size (1–2?µm) and the absence of associated inflammation in surrounding tissues. Electron microscopy remains the reference method of detection, but success with modified trichrome stains and polymerase chain reaction is encouraging.

There is no proven therapy for microsporidial intestinal infections. *E. intestinalis* infection usually responds to albendazole (adult dose: 400?mg bid PO for 3 wk). Fumagillin (adult dose: 20?mg tid PO for 2 wk) was effective in a small controlled study. Atovaquone and nitazoxanide have also been reported to decrease symptoms, but controlled clinical trials have not been performed. Improvement in underlying HIV infection with aggressive antiviral therapy also improves microsporidiosis symptoms.

Chapter 260 - Trichomoniasis (*Trichomonas vaginalis*)

Chandy C. John
Robert A. Salata

Trichomonas vaginalis is a sexually transmitted protozoan parasite that primarily causes symptomatic vaginitis in women.

Epidemiology.

An estimated 3 million American women have trichomoniasis each year; the occurrence in males is unknown. The incidence of trichomoniasis is highest among females with multiple sexual partners and in groups with the highest rates of

other sexually transmitted infections. Thus, patients found to harbor *T. vaginalis* should be screened for other sexually transmitted infections. *T. vaginalis* is recovered from more than 60% of female partners of infected men and 30–80% of male sexual partners of infected women. Trichomonads can survive for several hours in moist environments, but no case of transmission by indirect exposure has been documented. Vaginal trichomoniasis is rare until menarche; diagnosis in a younger child should raise the possibility of sexual abuse.

Trichomoniasis may be transmitted to neonates during passage through an infected birth canal. Neonatal infection is usually self-limited, but rare cases of neonatal vaginitis and respiratory infection have been reported.

Pathogenesis.

Infected vaginal secretions contain 10^1 –10^5 or more protozoa/mL. In fresh preparations, *T. vaginalis* are highly motile and pear shaped and are most easily recognized by their characteristic twitching motility. The organisms reproduce by binary fission and exist only as vegetative cells; cyst forms have not been described. *T. vaginalis* activates the alternative pathway of complement, attracting polymorphonuclear neutrophils, which in turn can kill the protozoon. Monocytes and macrophages have been shown to kill trichomonads in vitro, but their role in natural infection is uncertain. Durable protective immunity does not occur.

Clinical Manifestations.

The incubation period in females is 5–28 days. Symptoms may begin or exacerbate during menses. About 10–50% of women asymptomatically harbor the organism. Signs and symptoms most commonly associated with trichomoniasis include copious malodorous yellow vaginal discharge, vulvovaginal irritation, dysuria, and dyspareunia. On physical examination, a frothy discharge with vaginal erythema and cervical hemorrhages (**"strawberry cervix"**) may be seen. The vaginal discharge has a pH greater than 4.5. Unfortunately, none of these signs and symptoms alone or in combination is sensitive or specific enough to confidently establish a diagnosis of trichomoniasis. Abdominal discomfort is unusual and should prompt evaluation for pelvic inflammatory disease.

Most males carrying *T. vaginalis* are asymptomatic. The organism can be isolated in 5–15% of men with nongonococcal urethritis; these patients have symptoms that are indistinguishable from those of nongonococcal urethritis of other causes. Symptomatic males usually have dysuria and scant urethral discharge. Trichomonads occasionally cause epididymitis, prostatic involvement, and superficial penile ulceration. Infection in men is often self-limited, spontaneously resolving in 36% of men.

There is growing evidence that trichomoniasis is associated with poor pregnancy outcomes and gynecologic complications. In various studies, trichomoniasis has been shown to be associated with premature rupture of membranes, preterm labor, low birthweight, tubal infertility, and vaginal cuff cellulitis after hysterectomy. There is some evidence to suggest trichomoniasis increases the risk of HIV transmission.

Diagnosis.

The accurate diagnosis of trichomoniasis in both sexes is dependent on the demonstration of the protozoan in genital secretions. Trichomonads may be recognized in vaginal secretions by using the wet mount technique, which will identify 60–70% of infected females. Endocervical specimens are unreliable for diagnosis. Wet mount examination of material obtained by platinum loop from the anterior urethra will reveal the organism in 50–90% of infected men. Microscopic examination of urine sediment after prostatic massage is also of high yield in infected men. A negative wet mount finding does not exclude the diagnosis of trichomoniasis. Culture of the organism is the most sensitive (>95%) method of detection, especially for asymptomatic carriers, but is not routinely available. Enzyme-linked immunosorbent assay and direct fluorescence antigen testing of vaginal secretions are more sensitive than wet mount testing but less sensitive than culture for detection of *T. vaginalis* infection. DNA immunoblot and polymerase chain reaction testing of vaginal secretions appear to be highly sensitive and specific for detection of *T. vaginalis* infection but are not yet widely available.

Treatment.

Trichomoniasis is treated with a nitroimidazole. In the United States, metronidazole is used; in other countries tinidazole or ornidazole has been used with similar efficacy. Numerous studies have substantiated the efficacy of metronidazole as a single large dose (2?g PO) in adolescent females; an alternative regimen is metronidazole, 250?mg tid PO, or 375?mg bid PO, for 7 days. All regimens are equally efficacious, eradicating more than 90% of *T. vaginalis* infections. The single-dose regimen is associated with more frequent gastrointestinal side effects, but it ensures compliance. The recommended regimen for infected children is metronidazole, 15?mg/kg/24?hr (maximum 1?g) divided tid PO, for 7 days. Topical metronidazole gel is not efficacious when used as the sole therapy for *T. vaginalis* infection, but it may decrease symptoms in individuals with severe infection when used in conjunction with oral metronidazole. All sexual partners should be treated simultaneously to prevent reinfection.

Meta-analyses suggest that metronidazole therapy is safe in the first trimester of pregnancy, and several studies have reported the safety of this drug in the last two trimesters. *T. vaginalis* infection in any trimester of pregnancy should be treated with the 2-g oral single-dose regimen for metronidazole.

The number of putative metronidazole failures appears to be increasing. In some cases, metronidazole-resistant *T. vaginalis* has been documented. In most cases, failure is a consequence of reinfection from an untreated sexual partner or of noncompliance with multidose therapy. Options for cases of truly metronidazole-resistant *T. vaginalis* infection include higher-dose metronidazole, tinidazole, and topical paromomycin. Tinidazole appears to be the most effective treatment for resistant infection, but it is not available in the United States; topical paromomycin is less effective and has been associated with severe local side effects.

Chapter 261 - Leishmaniasis (*Leishmania*)

Peter C. Melby

The leishmaniases are a diverse group of diseases caused by intracellular protozoan parasites of the genus *Leishmania,* which are transmitted by phlebotomine sandflies. Multiple species of *Leishmania* organisms are known to cause human disease involving the skin and mucosal surfaces and the visceral reticuloendothelial organs. Cutaneous disease is generally mild but may cause cosmetic disfigurement. Mucosal and visceral leishmaniasis is associated with significant morbidity and mortality rates.

Etiology.

Leishmania are members of the Trypanosomatidae family and include two subgenera, *L. (Leishmania)* spp. and *L. (Viannia)* spp. The parasite is dimorphic, existing as a flagellate

promastigote in the insect vector and as an aflagellate amastigote that resides and replicates only within mononuclear phagocytes of the vertebrate host. Within the sandfly vector the promastigote changes from a noninfective procyclic form to an infective metacyclic stage. Fundamental to this transition are changes that take place in the terminal polysaccharides of the surface lipophosphoglycan (LPG), which allow forward migration of the infective parasites from the sandfly midgut to the mouth parts, from which they are inoculated into the host during a blood meal. The metacyclic LPG also plays an important role in the entry and survival of *Leishmania* in the mammalian host by conferring complement resistance and by facilitating entry into the macrophage by way of complement receptor 1. Once within the macrophage the promastigote transforms to an amastigote and resides and replicates within a phagolysosome. The parasite is resistant to the acidic, hostile environment of the macrophage and eventually ruptures the cell and goes on to infect other macrophages. Infected macrophages have a diminished capacity to initiate and respond to an inflammatory response, thus providing a safe haven for the intracellular parasite.

Epidemiology.

The leishmaniases are estimated to affect 10–50 million people in endemic tropical and subtropical regions on all continents except Australia and Antarctica. The different forms of the disease are distinct in their causes, epidemiologic characteristics, transmission, and geographic distribution. Localized cutaneous leishmaniasis (LCL) is caused by *L. (Leishmania) major* and *L. (L.) tropica* in North Africa, the Middle East, central Asia, and the Indian subcontinent. *L. (L.) aethiopica* is a cause of LCL and diffuse cutaneous leishmaniasis (DCL) in Kenya and Ethiopia. Visceral leishmaniasis (VL) in the Old World is caused by *L. (L.) donovani* in Kenya, Sudan, India, Pakistan, and China and by *L. (L.) infantum* in the Mediterranean basin, Middle East, and central Asia. *L. infantum* is also a cause of LCL (without visceral disease) in this same geographic distribution. *L. tropica* also has been recognized as an uncommon cause of visceral disease in the Middle East and India. In the New World, *L. (L.) mexicana* causes LCL in a region stretching from southern Texas through Central America. *L. (L.) amazonensis, L. (L.) pifanoi, L. (L.) garnhami,* and *L. (L.) venezuelensis* are causes of LCL in South America, in the Amazon basin, and northward. Members of the *Viannia* subgenus *(L. [V.] braziliensis, L. [V.] panamensis, L. [V.] guyanensis,* and *L. [V.] peruviana)* are causes of LCL from the northern highlands of Argentina northward to Central America. Members of the *Viannia* subgenus also cause mucosal leishmaniasis (ML) in a similar geographic distribution. VL in the New World is caused by *L. (L.) chagasi* (now considered by most taxonomists to be the same organism as *L. infantum),* which is distributed from Mexico (rare) through Central and South America. Like *L. infantum, L. chagasi* can also cause LCL in the absence of visceral disease. The leishmaniases may occur sporadically throughout an endemic region or may occur in epidemic focuses. With only rare exceptions, the *Leishmania* that primarily cause cutaneous disease do not cause visceral disease.

The maintenance of *Leishmania* in most endemic areas is through a zoonotic cycle in which humans are only incidentally infected. In general, the dermotropic strains in both the Old and New Worlds are maintained in rodent reservoirs, and the domestic dog is the usual reservoir for members of the *L. donovani* complex. The transmission between reservoir and sandfly is highly adapted to the specific ecologic characteristics of the endemic region. Human infections occur when human activities bring them in contact with the zoonotic cycle. Anthroponotic transmission, in which humans are the presumed reservoir, occurs with *L. tropica* in some urban areas of the Middle East and with *L. donovani* in India.

Over the past decade an increased number of cases have been reported from a number of long-standing endemic focuses, and large numbers of cases have been recognized in some new focuses. Severe epidemics with more than 100,000 deaths from VL have occurred in India and Sudan. The emergence of the leishmaniases in new focuses is the result of (1) movement of a susceptible population into existing endemic areas, usually because of agricultural or industrial development or timber harvesting; (2) increase in vector and/or reservoir populations as a result of agriculture development projects; (3) increase in anthroponotic transmission owing to rapid urbanization in some focuses; and (4) increase in sandfly density resulting from a reduction in malaria vector control programs.

Pathogenesis.

Cellular immune mechanisms determine resistance or susceptibility to infection with *Leishmania*. Resistance is mediated by expansion of the T helper 1 (Th1) cell population, with interferon-? production resulting in macrophage activation and parasite killing. Interleukin 12 (IL-12) plays a central role in the development of the protective Th1 response. Susceptibility is associated with expansion of IL-4–producing Th2 cells and/or the production of IL-10 and transforming growth factor-ß, which are potent inhibitors of macrophage activation. Patients with ML exhibit a hyperresponsive cellular immune reaction that may contribute to the prominent tissue destruction seen in this form of the disease. Patients with DCL or active VL demonstrate minimal or absent *Leishmania*-specific cellular immune responses, but these responses resume after successful therapy.

Within endemic areas people who have had a subclinical infection can be identified by a positive delayed-type hypersensitivity response to leishmanial antigens (**Montenegro skin test**). Subclinical infection occurs considerably more frequently than does active cutaneous or visceral disease. Host factors (genetic background, concomitant disease, nutritional status), parasite factors (virulence, size of the inoculum), and possibly vector-specific factors (vector genotype, immunomodulatory salivary constituents) influence the expression as either subclinical infection or active disease. Within endemic areas the prevalence of skin test result positivity increases with age and the incidence of clinical disease decreases with age, indicating that immunity is acquired in the population over time. Individuals with prior active disease or subclinical infection are usually immune to a subsequent clinical infection.

Clinical Manifestations.

The different forms of the disease are distinct in their causes, epidemiologic features, transmission, and geographic distribution.

LOCALIZED CUTANEOUS LEISHMANIASIS.

LCL (**Oriental sore**) can affect individuals of any age, but children are the primary victims in many endemic regions. It typically presents as one or a few papular, nodular, plaquelike, or ulcerative lesions that are usually located on exposed skin, such as the face and extremities. Rarely, more than 100 lesions have been recorded. The lesions typically begin as a small papule at the site of the sandfly bite, which enlarges to 1–3?cm in diameter and may ulcerate over the course of several weeks to months. The shallow ulcer is usually nontender and surrounded by a sharp, indurated, erythematous margin. There is no drainage unless a bacterial superinfection develops. Lesions caused by *L. major* and *L. mexicana* usually heal spontaneously after 3–6 mo, leaving a depressed scar. Lesions on the ear pinna caused by *L. mexicana,* called **chiclero ulcer** because they were common in chicle harvesters in Mexico and Central America, often follow a chronic, destructive course. In general, lesions caused by *L. (Viannia)* spp. tend to be larger and more chronic. Regional lymphadenopathy and palpable subcutaneous nodules or lymphatic cords, the so-called **sporotrichoid** appearance, are also more common when the patient is infected with organisms of the *Viannia* subgenus. If lesions do not become secondarily infected, there are usually no complications aside from the residual cutaneous scar.

DIFFUSE CUTANEOUS LEISHMANIASIS.

DCL is a rare form of leishmaniasis caused by organisms of the *L. mexicana*

---

complex in the New World, and *L. aethiopica* in the Old World. DCL manifests as large nonulcerating macules, papules, nodules, or plaques that often involve large areas of skin and may resemble lepromatous leprosy. The face and extremities are most commonly involved. Dissemination from the initial lesion usually takes place over several years. It is thought that an immunologic defect underlies this severe form of cutaneous leishmaniasis.

MUCOSAL LEISHMANIASIS.

ML (espundia) is an uncommon but serious manifestation of leishmanial infection resulting from hematogenous metastases to the nasal or oropharyngeal mucosa from a cutaneous infection. It is usually caused by parasites in the *L. (Viannia)* complex. Approximately half of the patients with mucosal lesions will have had active cutaneous lesions within the preceding 2 yr, but ML may not develop until years after resolution of the primary lesion. ML occurs in less than 5% of individuals who have, or have had, LCL caused by *L. (V.) braziliensis.* Patients with ML most commonly have nasal mucosal involvement and present with nasal congestion, discharge, and recurrent epistaxis. Oropharyngeal and laryngeal involvement is less common but associated with severe morbidity. Marked soft tissue, cartilage, and even bone destruction occurs late in the course of disease and may lead to visible deformity of the nose or mouth, nasal septal perforation, and tracheal narrowing with airway obstruction.

VISCERAL LEISHMANIASIS.

VL (kala-azar) typically affects children younger than 5 yr of age in the New World (*L. chagasi*) and Mediterranean region (*L. infantum*) and older children and young adults in Africa and Asia (*L. donovani*). Elegant epidemiologic studies performed in Brazil have defined the clinical evolution of this disease. After inoculation of the organism into the skin by the sandfly, the child may have a completely asymptomatic infection or an oligosymptomatic illness that either resolves spontaneously or evolves into active kala-azar. Children with asymptomatic infection are transiently seropositive but show no clinical evidence of disease. Children who are oligosymptomatic have mild constitutional symptoms (malaise, intermittent diarrhea, poor activity tolerance) and intermittent fever; most will have a mildly enlarged liver. In most of these children illness will resolve without therapy, but in approximately one fourth it will evolve to active kala-azar within 2–8 mo. Extreme incubation periods of several years have rarely been described. During the first few weeks to months of disease evolution the fever is intermittent, there is weakness and a loss of energy, and the spleen begins to enlarge. The classic clinical features of high fever, marked splenomegaly, hepatomegaly, and severe cachexia typically develop approximately 6 mo after the

onset of the illness, but a rapid clinical course over 1 mo has been noted in up to 20% of patients in some series. At the terminal stages of kala-azar the hepatosplenomegaly is massive, there is gross wasting, the pancytopenia is profound, and jaundice, edema, and ascites may be present. Anemia may be severe enough to precipitate heart failure. Bleeding episodes, especially epistaxis, are frequent. The late stage of the illness is often complicated by secondary bacterial infections, which frequently are a cause of death. A younger age at the time of infection and underlying malnutrition may be risk factors for the development and more rapid evolution of active VL. Death occurs in more than 90% of patients without specific antileishmanial treatment.

VL has been increasingly recognized as an opportunistic infection associated with HIV infection. Most cases have occurred in southern Europe and Brazil, but there is potential for many more cases as the endemic regions for HIV and VL converge. Leishmaniasis may also result from reactivation of a long-standing subclinical infection. Frequently there is an atypical clinical presentation of VL in HIV-infected individuals with prominent involvement of the gastrointestinal tract and absence of the typical hepatosplenomegaly.

A small percentage of patients who have previously been treated for VL will have diffuse skin lesions, a condition called **post–kala-azar dermal leishmaniasis (PKDL)**. These lesions may appear during or shortly after therapy (Africa) or up to several years later (India). The lesions of PKDL are hypopigmented, erythematous, or nodular and commonly involve the face and torso. They may persist for several months or for many years.

Diagnosis.

The development of one or several slowly progressive, nontender, nodular, or ulcerative lesions in a patient who had potential exposure in an endemic area should raise suspicion of LCL. Other diseases that should be considered include sporotrichosis, blastomycosis, chromomycosis, lobomycosis, cutaneous tuberculosis, atypical mycobacterial infection, leprosy, ecthyma, syphilis, yaws, and neoplasms. Histopathologic analysis of the LCL lesion shows intense chronic granulomatous inflammation involving the epidermis and dermis. Occasionally, neutrophils and even microabscesses can be seen. The lesions of DCL are characterized by dense infiltration with vacuolated macrophages containing abundant amastigotes.

ML is characterized by an intense granulomatous reaction with prominent tissue necrosis, which may include adjacent cartilage or bone. Other infections such as syphilis, tertiary yaws, histoplasmosis, paracoccidioidomycosis, as well as sarcoidosis, Wegener granulomatosis, midline granuloma, and carcinoma may have clinical features similar to those of ML.

A definitive diagnosis of leishmaniasis is established by the demonstration of amastigotes in tissue specimens or isolation of the organism by culture. Amastigotes can be identified in Giemsa-stained tissue sections, aspirates, or impression smears in about half of the cases of LCL but only rarely in the lesions of ML. Serologic tests for diagnosis of ML or LCL generally have a low sensitivity and specificity and offer little for diagnosis. Culture of a tissue biopsy or aspirate, best performed by using Novy-McNeal-Nicolle (NNN) biphasic blood agar medium, yields a positive finding in only about 65% of cases. A positive culture result allows speciation of the parasite (usually by isoenzyme analysis by a reference laboratory), which may have therapeutic and prognostic significance. Identification of parasites in impression smears, histopathologic sections, or culture medium is more readily accomplished in DCL than in LCL.

VL should be strongly suspected in the patient with prolonged fever, weakness, cachexia, marked splenomegaly, hepatomegaly, cytopenias, and hypergammaglobulinemia who has had potential exposure in an endemic area. The clinical picture may also be consistent with that of malaria, typhoid fever, miliary tuberculosis, schistosomiasis, brucellosis, amebic liver abscess, infectious mononucleosis, lymphoma, and leukemia. In VL there is prominent reticuloendothelial cell hyperplasia in the liver, spleen, bone marrow, and lymph nodes. Amastigotes are abundant in the histiocytes and Kupffer cells. Late in the course of disease, splenic infarcts are common, centrilobular necrosis and fatty infiltration of the liver occur, the normal marrow elements are replaced by parasitized histiocytes, and erythrophagocytosis is present. Results of smears or cultures of material from splenic, bone marrow, or lymph node aspirations are usually diagnostic. In experienced hands, splenic aspiration has a higher diagnostic sensitivity, but it is rarely performed in the United States because of the risk of bleeding complications. Serologic testing by enzyme immunoassay, indirect fluorescence assay, or direct agglutination is very useful in VL because of the very high level of antileishmanial antibodies. An enzyme-linked immunosorbent assay (ELISA) using a recombinant (K39) antigen has a sensitivity and specificity close to 100%. A negative serologic test result in an immunocompetent individual is strong evidence

against a diagnosis of VL. Serodiagnostic tests have positive findings in only about half of the patients who are co-infected with HIV.

Laboratory Findings.

Patients with cutaneous or mucosal leishmaniasis generally do not have abnormal laboratory results unless the lesions are secondarily infected with bacteria. Laboratory findings associated with classic kala-azar include anemia (hemoglobin 5–8?mg/dL), thrombocytopenia, leukopenia (2,000–3,000 cells/µL), elevated hepatic transaminase levels, and hyperglobulinemia (>5?g/dL) that is mostly immunoglobulin G (IgG).

Treatment.

Specific antileishmanial therapy is not routinely indicated for uncomplicated LCL caused by strains that have a high rate of spontaneous resolution and self-healing (*L. major, L. mexicana*). Lesions that are extensive, severely inflamed, or located where a scar would result in disability (near a joint) or cosmetic disfigurement (face or ear); that involve the lymphatics; or that do not begin healing within 3–4 mo should be treated. Cutaneous lesions suspected or known to be caused by members of the *Viannia* subgenus (New World) should be treated because of the low rate of

spontaneous healing and the potential risk of development of mucosal disease. Similarly, patients with lesions caused by *L. tropica* (Old World), which are typically chronic and nonhealing, should be treated. All patients with VL or ML should receive therapy.

The pentavalent antimony compounds (sodium stibogluconate [Pentostam, Wellcome Foundation, United Kingdom] and meglumine antimoniate [Glucantime, Rhafone-Poulenc, France]) have been the mainstay of antileishmanial chemotherapy for more than 40 yr. These drugs have similar efficacies, toxicities, and treatment regimens. Currently, for sodium stibogluconate (available in the United States from the Centers for Disease Control and Prevention, Atlanta, GA) the recommended regimen is 20?mg/kg/24?hr intravenously or intramuscularly for 20 days (for LCL and DCL) or 28 days (for ML and VL). Repeated courses of therapy may be necessary in patients with severe cutaneous lesions, ML, or VL. An initial clinical response to therapy usually occurs in the 1st week of therapy, but complete clinical healing (re-epithelialization and scarring for LCL and ML and regression of splenomegaly and normalization of cytopenias for VL) is usually not evident for weeks to a few months after completion of therapy. Cure rates with this regimen of 90–100% (LCL), 50–70% (ML), and 80–100% (VL) can be expected. Lower initial cure rates have been noted in patients from regions where clinical resistance to antimony therapy is common, such as India, East Africa, or some parts of Latin America. Relapses are common in patients who do not have an effective antileishmanial cellular immune response, such as those who have DCL or are co-infected with HIV. These patients often require multiple courses of therapy or a chronic suppressive regimen. When clinical relapses occur, they are usually evident within 2 mo after completion of therapy. Adverse effects of antimony therapy are dose and duration dependent and commonly include fatigue, arthralgias and myalgias (50%), abdominal discomfort (30%), elevated hepatic transaminase level (30–80%), elevated amylase and lipase levels (almost 100%), mild hematologic changes (slightly decreased leukocyte count, hemoglobin level, and platelet count) (10–30%), and nonspecific T-wave changes on electrocardiography (30%). Sudden death due to cardiac toxicity is extremely rare and usually associated with use of very high doses of pentavalent antimony.

Several other therapies have been used increasingly in the treatment of the leishmaniases. Amphotericin B desoxycholate and the newer lipid formulations are very useful in the treatment of antimony-unresponsive VL or ML. Amphotericin B desoxycholate at doses of 0.5–1.0?mg/kg each day or every other day for 14–20 doses achieved a cure rate for VL of close to 100%, but the renal toxicity commonly associated with amphotericin B was evident. The lipid formulations of amphotericin B are especially attractive for treatment of leishmaniasis because the drugs are concentrated in the reticuloendothelial system and are less nephrotoxic. Liposomal amphotericin B (3?mg/kg on days 1–5, and again on day 10) has been shown to be highly effective (90–100% cure rate) for treatment of VL in immunocompetent children, some of whom were refractory to antimony therapy. Treatment of VL with parenteral paromomycin has also shown some success, although it does not appear to be superior to either antimony or amphotericin B. Recombinant human interferon-? has been successfully used as an adjunct to antimony therapy in treatment of refractory cases of ML and VL. It is not effective alone and has the frequent side effects of fever and flulike symptoms. A phase II trial of miltefosine given orally at 50–150?mg/day for 4–6 weeks demonstrated a cure rate of more than 90%. Gastrointestinal side effects were frequent but did not require discontinuation of the drug. This may become the first oral drug that is effective in the treatment of VL. Pentamidine is an effective alternative treatment for LCL (especially in cases unresponsive to antimony) when given at 2–3?mg/kg every other day for four to seven doses. Treatment of ML and VL with pentamidine requires high doses and a long duration of therapy, making this drug less attractive than amphotericin B desoxycholate and the lipid formulations. Treatment of LCL with oral drugs has had only modest success. Ketoconazole has been effective in treating adults with LCL caused by *L. major, L. mexicana,* and *L. panamensis* but not *L. tropica* or *L. braziliensis.* Allopurinol has been used for many years in the treatment of CL, but recent controlled trials indicate that it is probably not effective as monotherapy. It may have a role as adjunct therapy with standard treatment regimens.

Prevention.

Personal protective measures should include avoidance of exposure to the nocturnal sandflies and, when necessary, the use of insect repellent and permethrin-impregnated mosquito netting. Where peridomiciliary transmission is present, community-based residual insecticide spraying has had some success in reducing the prevalence of leishmaniasis, but long-term effects are difficult to maintain. Control or elimination of infected reservoir hosts (e.g., seropositive domestic dogs) has had limited success. Where anthroponotic transmission is thought to occur, early recognition and treatment of cases are essential. A number of vaccines have been demonstrated to have efficacy in experimental models; vaccination of humans or domestic dogs may have a role in the control of the leishmaniases in the future.

Chapter 262 - African Trypanosomiasis (Sleeping Sickness; *Trypanosoma brucei* complex)

Robert A. Bonomo
Robert A. Salata

There are more than 66 million men, women, and children in close to 40 countries throughout sub-Saharan Africa who suffer from African trypanosomiasis, or sleeping sickness. The two forms of African trypanosomiasis are each caused by a protozoan parasite that causes a specific illness. One form, *Trypanosoma brucei gambiense*, causes a chronic infection lasting years and mostly affecting people who live in western and central Africa **(West African sleeping sickness).** A second form, *Trypanosoma brucei rhodesiense*, is an acute illness lasting several weeks and usually occurring in residents of eastern and southern Africa **(East African sleeping sickness).** Each year nearly 20,000–25,000 people are newly infected and 50,000 deaths from sleeping sickness occur. The greatest risk of contracting disease occurs in Uganda, Kenya, Tanzania, Malawi, Ethiopia, Zaire, and Botswana. It is at epidemic levels in Angola, the Democratic Republic of the Congo, Sudan, Cameroon, Ivory Coast, Tanzania, and Chad. In the Democratic Republic of the Congo, where 70% of the cases occur, the prevalence of African sleeping sickness has nearly reached that of AIDS. The length of time the insect vector is able to transmit disease is up to 6 mo, which is unappreciated. So far, 21 cases of East African sleeping sickness have been diagnosed in the United States since 1967.

Etiology.

Human trypanosomiasis, or African sleeping sickness, is a vector-borne disease caused by a parasitic trypanosome that is transmitted to humans through the bite of a tsetse fly of the genus *Glossina*, which is found only in Africa. The range of the tsetse fly includes watercourses, lakes, forests, and the savanna.

The tsetse fly feeds on the blood of humans and wild game animals and penetrates intact mucous membranes or skin. Humans usually contract the East African form of disease *(Trypanosoma brucei rhodesiense)* when they venture from towns to rural areas to visit woodlands or livestock. Once inoculated in the skin, the trypanosomes

proliferate and gradually invade all organs.

The West African form *(Trypanosoma brucei gambiense)* is usually contracted close to settlements. This latter form only requires a small vector population and thus will be particularly difficult to eradicate. The infective metacyclic forms of the trypanosomes possess no free flagella. After a period of local multiplication in the skin for 1–3 wk, long and slender forms can be seen in the peripheral blood; intermediate and stumpy forms also occur. These are flagellated forms with a well-developed undulating membrane. In the early stages of human infection, the organisms multiply rapidly in the blood and lymph nodes. They appear in waves in the peripheral blood, with each wave followed by a febrile crisis. The reappearance of another population of organisms in the blood heralds the formation of a new antigenic variant. Invasion of the central nervous system (CNS) occurs early in *T. brucei rhodesiense* infection but late in the Gambian form.

The insect intermediate vectors are species of the tsetse flies of the genus *Glossina*. Inside the flies, the organisms localize in the posterior part of the midgut, where they multiply for about 10 days and then gradually migrate anteriorly, where they attach to the walls of the salivary ducts and complete the final stages of development into the infective metacyclic forms. The life cycle within the tsetse fly takes 15–35 days.

Direct transmission to humans has also been reported, which occurs either mechanically through contact with the contaminated mouth parts of tsetse flies during feeding or congenitally to infants by way of the placenta of infected mothers.

Epidemiology.

Trypanosomiasis is one of the major public health problems in Africa. Unfortunately, data regarding the true incidence of the infection are unreliable. Political unrest and social change create favorable conditions for the emergence and resurgence of trypanosomiasis. Epidemics in rural areas pose a serious handicap to developing communities. Human trypanosomiasis in Africa occurs primarily in the region between latitudes 15 degrees north and 15 degrees south, which corresponds roughly to the area where the annual rainfall creates optimal climatic conditions for *Glossina* flies.

T. brucei rhodesiense infection is restricted to the eastern third of the endemic area in tropical Africa, stretching from Ethiopia to the northern boundaries of South Africa; *T. brucei gambiense* occurs mainly in the western half of the continent's endemic region. African trypanosomiasis affects more than 1 million people.

The insect intermediate vector plays a major role in determining the epidemiologic pattern of trypanosomiasis. Several *Glossina* species transmit the infection in different parts of tropical Africa. *Glossina* captured in endemic foci show a low rate of infection, usually less than 5%. In the Rhodesian form, which usually has an acute and often fatal course, chances of transmission to tsetse flies are greatly reduced. However, the ability of *T. brucei rhodesiense* to multiply enormously in the bloodstream of humans and to infect other species of mammals helps to maintain its life cycle.

T. brucei gambiense infection usually has a chronic protracted course with very low levels of parasitemia. Because of low rates of infection in tsetse flies, the life cycle of the Gambian form necessitates close and repeated contact between humans and insects to permit frequent biting. *T. brucei gambiense* is found in a variety of animal reservoirs that may play an important role in the endemic nature of the Gambian form of infection.

Pathogenesis.

The initial entry site of the organisms soon develops into a hard, painful, red nodule known as a **trypanosomal chancre**. Histologically, it contains long, thin trypanosomes multiplying beneath the dermis and is surrounded by a lymphocytic cellular infiltrate. Dissemination into the blood and lymphatic systems follows, with subsequent localization in the CNS. The histopathologic findings in the brain are those of meningoencephalitis, with increased cellularity of the pia-arachnoid owing to lymphocyte infiltration and perivascular cuffing. In chronic cases the appearance of **morular cells** (large, strawberry-like cells, supposedly derived from plasma cells) is the most characteristic finding.

A key feature of trypanosomiasis is the ability of the parasite to evade the immune system by antigenic variation. *T. brucei gambiense* regulates internal genetic switches to avoid immunologic attack by the host.

Clinical Manifestations.

The clinical presentations vary not only because of the two subspecies of organisms but also because of differences in host response in the indigenous population of endemic areas and in newcomers or visitors. Visitors usually suffer more from the acute symptoms, but in untreated cases death is inevitable for natives and visitors alike. Symptoms usually occur within 1–4 wk of infection. Initially, these are nonspecific and include personality changes, weight loss, ataxia, fatigue during the day, and insomnia at night. The clinical syndromes of African trypanosomiasis are best described as the trypanosomal chancre, hemolymphatic stage, and meningoencephalitic stage.

TRYPANOSOMAL CHANCRE.

The site of the tsetse fly bite may be the first presenting feature. A nodule or chancre develops

in 2–3 days and within 1 wk becomes a painful, hard, red nodule surrounded by an area of erythema and swelling. Nodules are commonly seen on the lower limbs but sometimes also on the head. They subside spontaneously in about 2 wk, leaving no permanent scar.

HEMOLYMPHATIC STAGE.

The most common presenting features of acute African trypanosomiasis occur at the time of invasion of the bloodstream by the parasites, 2–3 wk after infection. Irregular episodes of fever, each lasting 1–7 days, are the usual early feature, frequently accompanied by headache, sweating, and generalized lymphadenopathy. Attacks may be separated by symptom-free intervals of days or even weeks. Painless, nonmatted lymphadenopathy, most commonly of the posterior cervical and supraclavicular nodes, is one of the most constant signs, particularly in the Gambian form. A common feature of trypanosomiasis in whites is the presence of blotchy, irregular, nonpruritic, erythematous macules, which may appear any time after the first febrile episode, usually within 6–8 wk. The majority of macules have a normal central area, giving the rash a circinate outline. This rash is seen mainly on the trunk and is evanescent, fading in one place only to appear at another site. Examination of the blood during this stage may show anemia, leukopenia with relative monocytosis, and elevated levels of immunoglobulin M (IgM).

MENINGOENCEPHALITIC STAGE.

Neurologic symptoms and signs are generally nonspecific, including irritability, insomnia, and irrational and inexplicable anxieties with frequent changes in mood and personality. Neurologic symptoms may precede invasion of the CNS by the organisms. In untreated *T. brucei rhodesiense* infections, CNS invasion occurs within 3–6 wk and is associated with recurrent bouts of headache, fever, weakness, and signs of acute toxemia. Tachycardia may be evidence of myocarditis. Death occurs in 6–9 mo as a result of secondary infection or cardiac failure.

In the Gambian form, cerebral symptoms can be expected to appear within 2 yr after the onset of acute symptoms. A general increase in drowsiness during the day and insomnia at night reflect the continuous progression of infection, which may be further evidenced by increasing anemia, leukopenia, and wasting of body musculature. Patients with chronic Gambian trypanosomiasis have an increased susceptibility to secondary infections.

The chronic, diffuse meningoencephalitis without localizing symptoms is the form commonly known as **sleeping sickness.** Drowsiness and an uncontrollable urge to sleep are the major features of this stage of the disease and may become almost continuous in the terminal stages. Associated signs and symptoms, including tremor or rigidity with stiff and ataxic gait, suggest involvement of the basal ganglia. Psychotic changes occur in almost one third of untreated patients.

Diagnosis.

Definitive diagnosis can be established during the early stages by examination of a fresh, thick blood smear, which permits visualization of the motile active forms. In the bloodstream, the parasite can be detected using a variety of sensitive techniques: quantitative buffy coat smears and mini anion exchange resins are common examples. The **Card Agglutination Trypanosomiasis Test (CATT)** is of value for epidemiologic purposes and to screen for *T. brucei gambiense*. Dried, Giemsa-stained smears should be examined for the detailed morphologic features of the organisms. If a thick blood or buffy-coat smear yields a negative finding, a simple concentration method may help; 10?mL of heparinized blood is added to 30?mL of 0.87% ammonium chloride, the mixture is centrifuged at 1,000?g for 15?min, and the sediment is examined fresh or by staining dried smears. Aspiration of an enlarged lymph node can also be used to obtain material for parasitologic examination. For every positive result a sample of cerebrospinal fluid should also be examined for the organisms.

Treatment.

The choice of chemotherapeutic agents for treatment depends on the stage of the infection and the causative organisms. The hematogenous forms of both Rhodesian and Gambian trypanosomiasis are susceptible to the action of suramin, which is available as a 10% solution for intravenous administration. A test dose (10?mg for children; 100–200?mg for adults) should first be administered intravenously to detect the rare idiosyncratic reactions of shock and collapse. The dose for subsequent IV injections is 20?mg/kg (maximum: 1?g) administered on days 1, 3, 7, 14, and 21. Suramin is nephrotoxic; therefore, urine should be examined before each administration. The presence of marked proteinuria, blood, or casts is a contraindication to continuation of therapy with suramin. Pentamidine isethionate (4?mg/kg/24?hr IM for 10 days) is better tolerated than suramin.

If CNS invasion is present, melarsoprol should be used. Melarsoprol is an investigational arsenical compound with trypanosomicidal effects. It has been used outside the United States for the treatment of late hemolymphatic and CNS African trypanosomiasis. Treatment of children is initiated with melarsoprol 0.36?mg/kg/24?hr IV, with the dose gradually increased every 1–5 days to 3.6?mg/kg IV; treatment usually necessitates 10 doses (18–25?mg/kg total dose). Treatment of adults is by melarsoprol, 2–3.6?mg/kg IV for 3 days, and, after 1 wk, 3.6?mg/kg IV for 3 days, which is repeated after 10–21 days. Recommended guidelines suggest 18–25?mg/kg total over 1 month. Mild reactions such as fever and pains in the chest or abdomen may rarely occur immediately or very soon after administration. The most important and serious toxic effects are encephalopathy and, less commonly, exfoliative dermatitis.

Eflornithine has been reported to be effective in late-stage West African sleeping sickness or in instances where CNS involvement is suspected or present. It is more effective against *T. brucei gambiense* and variably effective against *T. brucei rhodesiense*. It is in short supply and is given as 400?mg/kg/24?hr divided q6h IV. The World Health Organization has contacted with a number of pharmaceutical corporations to produce and donate large quantities of eflornithine. Pentamidine has been used successfully as a prophylactic drug. A single injection of pentamidine (3–4?mg/kg IM) will provide protection against Gambian trypanosomiasis for at least 6 mo, although the effect against the Rhodesian form is uncertain.

Prevention.

Currently, an effective vaccine or prophylactic therapy is not available. The control of trypanosomiasis in endemic areas of Africa depends on recognition, effective therapy of human infections, and control of the vector. This is complicated by the logistics of applying the available preventive measures in areas of political conflicts and massive population movements.

The World Health Organization and the Centers for Disease Control and Prevention have recommended several measures. Vector control programs to control *Glossina* is critical. The use of screens, traps, and sanitary measures is fundamental. Encouraging neutral colored clothing that is not attractive to the tsetse fly may reduce bites. Using serology and parasitologic methods, mobile medical surveillance of the population at risk by specialized staff is critical. The creation of referral centers for evaluation and treatment is needed. Ground spraying of insecticides, aerial spraying, and the use of cloth and live animal baits are successful. Transgenic techniques to restrict the ability of the tsetse fly to survive and transmit pathogens are also being developed.

Difficulties to be anticipated in the treatment of sleeping sickness are drug resistance and continued change in range of antigenic expression. Vector control strategies are potentially the most promising but most difficult to implement.

Chapter 263 - American Trypanosomiasis (Chagas Disease; *Trypanosoma cruzi*)

Robert A. Bonomo
Robert A. Salata

Chagas disease (American trypanosomiasis) is a zoonotic illness caused by the blood-sucking triatomine insects, or **kissing bugs,** that transmit the parasitic, hemoflagellate protozoan *Trypanosoma cruzi.* This illness is found only in the Western hemisphere. Chagas first described this illness in 1911 in a Brazilian child who had fever, anemia, and lymphadenopathy.

Etiology.

There are nearly 20 species of *Trypanosoma*. Only 4 species infect humans: *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense* (the agents of African sleeping sickness), *Trypanosoma cruzi* (the agent of Chagas disease), and *Trypanosoma rangeli*. *T. cruzi* has three recognizable morphogenetic phases: amastigotes, trypomastigotes, and epimastigotes. **Amastigotes** are the intracellular forms found in mammalian tissues and are spherical and have a short flagellum but form clusters of oval shapes **(pseudocysts)** within infected tissues. **Trypomastigotes** are the extracellular nondividing forms and are spindle shaped, are 20?µm long, and possess a large **kinetoplast**, which is a large complex mitochondrion containing DNA that stains darkly on routine smears. A flagellum arises from the blepharoplast and extends along the outer edge of the undulating membrane until it reaches the anterior end of the body. Trypomastigotes are found in blood and are responsible for transmission of infection to the insect vector and for cell-to-cell spread of infection. **Epimastigotes** are found in the midgut of the blood-sucking insects *Triatoma infestans, Rhodnius prolixus,* and *Panstrongylus megistus.* Epimastigotes multiply in the midgut and rectum of arthropods and differentiate into metacyclic trypomastigotes. Metacyclic trypomastigotes, the infectious form for humans, are released onto the skin of a human when the insect defecates close to the site of a bite. Hence, this is an infection caused by contamination, not inoculation. The trypomastigotes enter the skin or damaged mucous membranes and either enter host cells or are phagocytized by

macrophages. Once in the host, they multiply intracellularly as amastigotes and are released into the host's circulation when the cell dies. The bloodborne trypomastigotes circulate until they enter another host cell or are taken up by the bite of another insect, completing the life cycle.

Epidemiology.

Chagas disease is endemic in Mexico and South America, particularly Brazil, Argentina, Uruguay, Chile, and Venezuela. The World Health Organization estimates that Chagas disease affects close to 20 million people, primarily children and young adults. This insect-transmitted illness frequently is asymptomatic and is essentially untreatable, with infection persisting for life. Because of its prevalence, infection by *T. cruzi* is regarded as the most important endemic disease in South America. From 45,000–70,000 individuals die annually as a result of this infection. Up to 30% of persons with chronic *T. cruzi* infection will acquire symptomatic disease. It is still unclear how this parasitic protozoan escapes the immune system because antigenic variation is not reported.

Although reduviid insects can be found in warmer regions of the United States as far north as Maryland, cases of Chagas disease are extremely rare, owing to the higher standard of domestic housing. Most U.S. cases are associated with laboratory accidents. Approximately 100,000 immigrants living in the United States from endemic countries may be infected with *T. cruzi*, and several cases in immigrants have been reported in American cities.

T. cruzi infection is primarily a zoonosis. Humans are not absolutely required to maintain the parasite in nature. *T. cruzi* has been isolated from numerous species of animals (large sylvan reservoir). The vectors transmitting this disease are found in rural, wooded areas and become infected by ingesting blood from humans or animals that possess circulating trypomastigotes. Humans become infected when land in enzootic areas is opened up for agricultural or commercial purposes. As the natural reservoir is disrupted, vectors take up residence in domestic areas and establish a cycle of transmission to animals and humans.

The presence of reservoirs and vectors of *T. cruzi* and the socioeconomic and educational levels of the population are the most important risk factors in disease transmission to humans, which occurs by means of insect vectors. The arthropod vectors for *T. cruzi* are the reduviid insects, variably known as wild bedbugs, assassin bugs, or kissing bugs. Housing conditions are very important in the transmission chain; the incidence and prevalence of infection depend on the adaptation of the triatomids to human dwellings as well as the vector capacity of the species. The animal reservoirs of reduviid bugs are dogs, cats, rats, opossum, guinea pigs, monkeys, bats, and raccoons. In South America, uncontrolled deforestation, increased migration of infected humans from endemic to nonendemic areas, and the presence of domestic reservoir hosts facilitate spread.

Humans can be infected transplacentally, as occurs in 10.5% of infected mothers, causing congenital Chagas disease that is associated with premature birth, fetal wastage, and placentitis. Disease transmission may also occur through blood transfusions in endemic areas from asymptomatic blood donors. Seropositivity rates in blood donors from endemic areas are more than 20%. The risk of transmission through a single blood transfusion from a chagasic donor is 13–23%. Currently, blood in the southern United States is not screened for *T. cruzi*. Percutaneous injection as a result of laboratory accidents is also a documented mode of transmission. Oral transmission through contaminated food has been reported. Although breast-feeding is a very uncommon mode of transmission, women with acute infections should not nurse until they have been treated.

Pathogenesis.

Although the pathogenesis of chronic Chagas disease is unknown, two main mechanisms have been proposed: (1) direct tissue destruction by the parasite and (2) development of an inflammatory reaction resulting from an allergic response to parasitic antigens absorbed by host cells or an autoimmune reaction resulting from shared antigens between host and parasite.

At the site of entry (puncture site), polymorphonuclear neutrophils, lymphocytes, macrophages, and monocytes infiltrate. *T. cruzi* are engulfed by macrophages and are sequestered in membrane-bound vacuoles. Parasite attachment and phagocytosis by macrophages are mediated by protease-sensitive receptors on the surface of the macrophage. Trypanosomes lyse the phagosome membrane, escape into the cytoplasm, and replicate. A local tissue reaction develops (the **chagoma**), and the process extends to a local lymph node. Blood forms appear next, and the process disseminates.

T. cruzi strains demonstrate selective parasitism for certain tissues. Most strains are myotropic, invading smooth, skeletal, and heart muscle cells. Attachment is mediated by specific receptors on the trypomastigotes that attach to complementary glycoconjugates on the host cell surface. Attachment to cardiac muscle results in inflammation of the endocardium and myocardium, edema, focal necrosis in the contractile and conducting systems, periganglionitis, and lymphocytic inflammation. The heart becomes enlarged, and endocardial thrombosis or aneurysm may result. Right bundle branch block is also common. Trypanosome parasites

---

also attach to neural cells and reticuloendothelial cells. In patients with gastrointestinal tract involvement, myenteric plexus destruction leads to organ dilatation (megaesophagus and megacolon).

Immunologic mechanisms for control of parasitism and resistance are not completely understood. Despite strong acquired immunity, there is no parasitologic cure. Antigenic variation that is typical of African trypanosomiasis is not seen with American trypanosomiasis. Antibodies involved with resistance to *T. cruzi* are related to the phase of infection. Immunoglobulin G (IgG) antibodies, probably to several major surface antigens, mediate immunophagocytosis of the parasite by macrophages. Conditions associated with depression of cell-mediated immunity increase the severity of infection with *T. cruzi*. Macrophages probably play a major role in protection against *T. cruzi* infection, especially in the acute phase. Interferon-? stimulates macrophage killing of amastigotes through oxidative mechanisms.

Clinical Manifestations.

Chagas disease occurs in acute and chronic forms. **Acute Chagas disease** in children is usually asymptomatic or is associated with a mild febrile illness characterized by malaise, facial edema, and lymphadenopathy. Infants often demonstrate local signs of inflammation at the site of parasite entry (chagomas). Approximately 50% of children come to medical attention with Romaña sign (unilateral, painless eye swelling), conjunctivitis, and preauricular lymphadenitis. Patients complain of fatigue and headache. Fever can persist for 4–5 wk. More severe systemic presentations can occur in children younger than 2 yr of age and include lymphadenopathy, hepatosplenomegaly, and meningoencephalitis. A cutaneous morbilliform eruption can accompany the acute syndrome. Anemia, lymphocytosis, hepatitis, and thrombocytopenia have been described.

The heart, central nervous system, peripheral nerve ganglia, and reticuloendothelial system are often heavily parasitized. The heart is the primary target organ. The intense parasitism can result in acute inflammation and in four-chamber cardiac dilatation. Diffuse myocarditis and inflammation of the conduction system lead to the development of fibrosis. Histologic examination reveals the characteristic pseudocysts, which are the intracellular aggregates of amastigotes.

Intrauterine infection in pregnant women can cause spontaneous abortion or premature birth. In children with congenital infection, severe anemia, hepatosplenomegaly, jaundice, and convulsions can mimic congenital cytomegalovirus infection, toxoplasmosis, and erythroblastosis fetalis. *T. cruzi* can be visualized in the cerebrospinal fluid in meningoencephalitis. Children usually undergo spontaneous remission in 8–12 wk and enter an indeterminate phase with lifelong low-grade parasitemia and development of antibodies to many *T. cruzi* cell surface antigens. Mortality rate is 5–10%; deaths are caused by acute myocarditis with resultant heart failure, or meningoencephalitis. Acute Chagas disease must be differentiated from malaria, schistosomiasis, visceral leishmaniasis, brucellosis, typhoid fever, and infectious mononucleosis.

Chronic Chagas disease may be asymptomatic or symptomatic. The most common presentation of chronic *T. cruzi* infection is cardiomyopathy, manifested by congestive heart failure, arrhythmia, and thromboembolic events. Abnormalities detected electrocardiographically include partial or complete atrioventricular block and right bundle branch block. Left bundle branch block is unusual. Pathologic examination of infected heart muscle reveals muscle atrophy, myonecrosis, myocytolysis, fibrosis, and lymphocytic infiltration. Myocardial infarction has been reported and may be secondary to left apical aneurysm embolization or necrotizing arteriolitis of the microvasculature. Left ventricular apical aneurysms are pathognomonic of chronic chagasic cardiomyopathy.

Autonomic nervous system abnormalities have also been implicated in Chagas cardiomyopathy. The reduction in acetylcholine and choline acetyltransferase levels in experimental *T. cruzi* infection lends support to this notion.

Autoimmune abnormalities have been reported in Chagas cardiomyopathy. Depletion of CD8 cells accelerates infection. *T. cruzi*–infected human peripheral blood mononuclear and endothelial cells synthesize increased levels of interleukin 1ß (IL-1ß), IL-6, and tumor necrosis factor (TNF). These cytokines result in increasing leukocyte recruitment and smooth muscle cell proliferation, which may be responsible for some of the manifestations of the disease. Viral myocarditis, rheumatic heart disease, and endomyocardial fibrosis can mimic chronic chagasic cardiomyopathy.

The gastrointestinal manifestations of chronic Chagas disease occur in 8–10% of patients and involve a diminution in Auerbach plexus and Meissner plexus. There are also preganglionic lesions and a reduction in the number of dorsal motor nuclear cells of the vagus nerve. Characteristically, this involvement presents clinically as megaesophagus and megacolon. Sigmoid dilatation, volvulus, and fecalomas are often found in megacolon. Loss of ganglia in the esophagus results in abnormal dilatation (megaesophagus); the esophagus can reach up to 26 times its normal weight and hold up to 2?L of excess fluid. Megaesophagus presents as dysphagia, odynophagia, and cough. Esophageal body abnormalities occur independently of lower esophageal dysfunction. Megaesophagus can lead to esophagitis and cancer of the esophagus. Aspiration pneumonia and pulmonary tuberculosis are more common in patients with megaesophagus.

Autonomic dysfunction and peripheral neuropathy can occur. Central nervous system involvement in Chagas disease is uncommon. If granulomatous encephalitis occurs in the acute infection it is usually fatal.

IMMUNOCOMPROMISED PERSONS.

T. cruzi infections in immunocompromised persons are caused by transmission from an asymptomatic donor of blood products or activation of prior infection by immunosuppression. Organ donation to allograft recipients can result in a devastating form of the illness. Cardiac transplantation for Chagas cardiomyopathy has resulted in reactivation, despite prophylaxis and postoperative treatment with benznidazole. HIV infection also leads to reactivation; cerebral lesions are more common in these patients and can mimic those of toxoplasmic encephalitis. In immunocompromised patients at risk for reactivation, serologic testing and close monitoring are necessary.

Diagnosis.

A careful history with attention to geographic origin and travel is important. Microscopic examination of a fresh preparation of a peripheral blood smear or a Giemsa-stained smear during the acute phase of illness will demonstrate motile trypanosomes, which is diagnostic for Chagas disease. These are only seen in the peripheral blood in the first 6–12 wk of the illness. Buffy coat smears may improve yield.

Most persons seek medical attention during the chronic phase of the disease, when parasites are not found in the bloodstream and clinical symptoms are not diagnostic. Serologic testing is also a good means of diagnosis. Complement fixation is considered the most reliable immunodiagnostic method for establishing the diagnosis. Specific IgM antibodies can be detected using an enzyme-linked immunosorbent assay (ELISA) and indirect fluorescent antibody test. Indirect

fluorescent antibody testing is also very accurate and can be used to distinguish acute chagasic infection, with IgM antibodies, from chronic infection, with only IgG antibodies. These tests are available from the Centers for Disease Control and Prevention (CDC). Because false-positive reactions can result from other infections (e.g., malaria, syphilis, and leishmaniasis), it is recommended that a minimum of two independent serologic tests be performed.

Nonimmunologic methods of diagnosis are also available. Mouse inoculation has been used when repeated peripheral smear results are negative. Xenodiagnosis, allowing uninfected reduviid bugs to feed on a patient's blood and examining the intestinal contents of those bugs 30 days after the meal, detects 100% of cases. Detection assays using polymerase chain reaction (PCR) amplification of nuclear and kinetoplast DNA (kDNA) sequences are in development. Parasites may be cultivated in Nicole-Novy-MacNeal (NNN) media. PCR has a sensitivity of 96–100% and is able to detect a single parasite in 20?mL of blood. Chemiluminescent ELISAs are being developed and are also reported to be highly sensitive and specific.

Treatment.

Drug treatment for *T. cruzi* infection is generally limited to two drugs: nifurtimox and benznidazole. Both are effective against trypomastigotes and amastigotes and have been used to eradicate parasites in the acute stages of infection. The results vary according to the phase of Chagas disease, the period of treatment, the dose, the age of the patient, and the geographic origin of the patient. Neither drug is safe in pregnancy.

Nifurtimox has been used most extensively, but whether it is effective in the chronic phase of the illness is uncertain. The treatment regimen for children 1–10 yr of age is 15–20?mg/kg/24?hr divided qid PO for 90 days; for children, 11–16 yr of age, 12.5–15?mg/kg/24?hr divided qid PO for 90 days; and for children older than 16 yr of age, 8–10?mg/kg/24?hr divided tid–qid PO for 90–120 days. Nifurtimox interferes with the carbohydrate metabolism of the parasite by disrupting pyruvic acid synthesis. Because *T. cruzi* is partially deficient in free radical detoxification mechanisms it is susceptible to such intermediates. Nifurtimox has been associated with weakness, anorexia, gastrointestinal disturbances, toxic hepatitis, tremors, seizures, and hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. The mode of action of nifurtimox involves generation of nitro-anion radicals by nitroreductases that lead to reactive intermediates. Nifurtimox is available from the CDC.

Benznidazole is a nitroimidazole derivative that is also used and may be more effective than nifurtimox. The mode of action of benznidazole is more complex than that of nifurtimox. The recommended treatment regimen for children younger than 12 yr of age is 10?mg/kg/24?hr divided bid PO for 60 days, and for those 12 yr of age or older, 5–7?mg/kg/24?hr PO for 60 days. In one randomized, double-blind, placebo-controlled trial in a rural area of Brazil, a 60-day course of benznidazole was studied in the treatment of early chronic phase *T. cruzi* infection in schoolchildren 7–12 yr of age. The efficacy of benznidazole was 55.8% in producing negative seroconversion. This drug is also associated with significant toxicities, including rash, photosensitivity, peripheral neuritis, and granulocytopenia and thrombocytopenia. Of some concern are the reports that detail the development of lymphomas in laboratory animals treated with benznidazole. This finding has not been reported in humans.

Regardless of the clinical status or the time elapsed since infection, patients with chronic asymptomatic Chagas disease should be treated with nifurtimox or benznidazole. Nitroimidazolic derivatives substantially reduced and significantly modified parasite related outcomes compared with placebo. Benznidazole has the greatest effect. It is yet unclear if recombinant interferon-? should be used in immunocompromised patients.

A number of other agents have also been tried. Allopurinol, a drug that inhibits hypoxanthine oxidase, has also been used and has been shown to reduce parasitemia. It is ineffective in the acute phase. Many other drugs that are directed against novel targets are in experimental trials.

Biochemical differences between the metabolism of American trypanosomes and that of mammalian hosts may be exploited for chemotherapy. These trypanosomes are very sensitive to oxidative radicals, and they do not possess catalase or glutathione reductase/glutathione peroxidase, which are key enzymes in scavenging free radicals. All trypanosomes also have an unusual reduced nicotinamide-adenine dinucleotide phosphate (NADPH)–dependent disulfide reductase. For this reason, drugs that stimulate H_2O_2 generation or prevent its utilization are potential trypanocidal agents.

Treatment of heart failure and arrhythmia, as well as prevention of thromboembolism, requires the use of diuretics, antiarrhythmics, and anticoagulants. Digitalis toxicity occurs frequently in patients with Chagas cardiomyopathy. Pacemakers may be necessary in cases of severe heart block. A light, balanced diet is recommended for megaesophagus. Surgery or dilation of the lower esophageal sphincter treats megaesophagus; pneumatic dilation is the superior mode of therapy. Nitrates and nifedipine have been used to reduce lower esophageal sphincter pressure in patients with megaesophagus. Treatment of megacolon is surgical and symptomatic. Treatment of meningoencephalitis is also supportive.

In accidental infection when parasitic penetration is certain, treatment should be immediately initiated and continued for 10–15 days. Blood is usually collected and serologic samples tested for seroconversion at 15, 30, and 60 days.

Prevention.

No vaccine or prophylactic therapy is available. Education of residents in endemic areas, use of bed nets, use of insecticides such as dieldrin or lindane, and destruction of adobe houses that harbor reduviid bugs are effective methods to control the bug population. Synthetic pyrethroid insecticides help keep houses free of vectors for 2 yr and have low toxicity for humans. Paints incorporating insecticides have also been used. Vaccine development has been fruitless. Prophylactic therapy with nifurtimox or benznidazole should be considered only for laboratory accidents. Because immigrants can carry this disease to nonendemic areas, serologic testing

should be performed in blood donors from high-risk populations. Potential seropositive donors can be identified by determining whether they have been or have spent extensive time in an endemic area. Questionnaire-based screening of potentially infected blood donors from areas endemic for infection can reduce the risk of transmission.

Blood transfusions in endemic areas are a significant risk. Gentian violet, an amphophilic cationic agent that acts photodynamically, has been used to kill the parasite in blood. Photoirradiation of blood containing gentian violet and ascorbate generates free radicals and superoxide anions that are trypanocidal. Mepacrine and maprotiline have also been used to eradicate the parasite in blood transfusions. Potential organ donors from endemic areas should also be screened; seropositivity should be considered a contraindication to organ donation. Although cardiac transplantation has been successful in chagasic patients, further study is needed. An international program has been established in endemic areas (Argentina, Bolivia, Brazil, Uruguay, Paraguay, and Chile) to help eliminate transmission. Screening of emigrants from endemic areas may significantly reduce transmission.

Chapter 264 - Malaria (*Plasmodium*)

Peter J. Krause

Malaria is an acute and chronic illness characterized by paroxysms of fever, chills, sweats, fatigue, anemia, and splenomegaly. It has played a major role in human history, having arguably caused more harm to more people than any other infectious disease. Malaria is of overwhelming importance in the developing world today, with an estimated 300 million cases and more than 1 million deaths each year. Most malarial deaths occur in infants and young children. Although there is no endemic malaria in the United States, approximately 1,000 imported cases are recognized each year. Physicians practicing in nonendemic areas should consider the diagnosis of malaria in any febrile child who has returned from a malaria-endemic area within the previous year because delay in diagnosis and treatment can result in severe illness or death.

Etiology.

Malaria is caused by intracellular *Plasmodium* protozoa transmitted to humans by female *Anopheles* mosquitoes. Four species of *Plasmodium* cause malaria in humans: *P. falciparum, P. malariae, P. ovale,* and *P. vivax.* Malaria also can be transmitted through blood transfusion, by use of contaminated needles, and from a pregnant woman to her fetus. The risk of blood transmission is small and decreasing in the United States but may occur by way of whole blood, packed red blood cells, platelets, leukocytes, and organ transplantation.

Epidemiology.

Malaria is a worldwide problem with transmission occurring in over 100 countries with a combined population of over 1.6 billion people. The principal areas of transmission are Africa, Asia, and South America. *P. falciparum* and *P. malariae* are found in most malarious areas. *P. falciparum* is the predominant species in Africa, Haiti, and New Guinea. *P. vivax* predominates in Bangladesh, Central America, India, Pakistan, and Sri Lanka. *P. vivax* and *P. falciparum* predominate in Southeast Asia, South America, and Oceania. *P. ovale,* the rarest species, is transmitted primarily in Africa. Transmission of malaria has been eliminated in most of North

America (including the United States), Europe, and the Caribbean, as well as Australia, Chile, Israel, Japan, Korea, Lebanon, and Taiwan.

Most cases of malaria in the United States or Europe consist of previously infected visitors from endemic areas, citizens who travel to endemic areas without taking appropriate chemoprophylactic drugs, and a small number of transfusion-associated and congenital cases. Since 1986, 11 indigenous cases have been documented in the United States. It is likely that untreated patients with malaria acquired in an endemic country traveled to the United States and infected local mosquitoes that subsequently transmitted the disease to others.

Pathogenesis.

Plasmodium species exist in a variety of forms and have a complex life cycle that enables them to survive in different cellular environments in the human host (asexual phase) and the mosquito vector (sexual phase). A marked amplification of *Plasmodium* organisms from approximately 10^2 to as many as 10^{14} occurs during a two-step process in humans. The first occurs in the cells of the liver **(exoerythrocytic phase)** and the second in the red cells **(erythrocytic phase)**. The exoerythrocytic phase begins with inoculation of sporozoites into the bloodstream by a female *Anopheles* mosquito. Within minutes, the sporozoites enter the hepatocytes of the liver, where they develop and multiply asexually. The parasite is referred to as a **schizont** at this stage. After 1–2 wk, the hepatocytes rupture and release thousands of merozoites into the circulation. The tissue schizonts of *P. falciparum* and *P. malaria* rupture once, and none persists in the liver. There are two types of tissue schizonts for *P. ovale* and *P. vivax*. The primary type ruptures in 6–9 days while a secondary type remains dormant in the liver cell for weeks, months, or as long as 5 yr before releasing merozoites, and thereby causing *relapses* of infection. The erythrocytic phase of *Plasmodium* asexual development begins when the merozoites from the liver penetrate erythrocytes. Once inside the erythrocyte, the parasite transforms into the **ring form**, which then enlarges to become a trophozoite. These latter two forms can be identified with Giemsa stain on blood smear, the primary means of confirming the diagnosis of malaria (Fig. 264–1). The trophozoite multiplies asexually to produce a number of small erythrocytic merozoites. Merozoites are released into the bloodstream when the erythrocyte membrane ruptures, a process associated with the production of fever. Over time, some of the merozoites develop into male and female gametocytes. It is the gametocytes that complete the *Plasmodium* life cycle when they are ingested during a blood meal by the female *Anopheline* mosquito. The male and female gametocytes fuse to form a zygote in the stomach cavity of the mosquito. After a series of further transformations, sporozoites enter the salivary gland of the mosquito and are inoculated into a new host with the next blood meal.

Four important pathologic processes have been identified in patients with malaria: (1) fever, (2) anemia, (3) immunopathologic events, and (4) tissue anoxia resulting from cytoadherence of infected erythrocytes. Fever occurs when erythrocytes rupture and release merozoites into the circulation. Anemia is caused by hemolysis, sequestration of erythrocytes in the spleen and other organs, and bone marrow depression. Immunopathologic events that have been documented in patients with malaria include polyclonal activation resulting in both hypergammaglobulinemia and the formation of immune complexes, immunodepression, and release of cytokines such as tumor necrosis factor that may be responsible for much of the pathology of the disease. Cytoadherence of infected erythrocytes to vascular endothelium occurs in *P. falciparum* malaria. It may lead to obstruction of blood flow and capillary damage with resultant vascular leakage of protein and fluid, edema, and tissue anoxia in the brain, heart, lung, intestine, and kidney.

Immunity after *Plasmodium* species infection is incomplete so that severe disease is averted but complete eradication or prevention of future infection is not achieved. In some cases parasites circulate in small numbers for a long time but are prevented from rapidly multiplying and causing severe illness. Repeated episodes of infection occur because the parasite has developed a number of immune evasive strategies, such as intracellular replication, rapid antigenic variation, and alteration of the host immune system that includes partial immune

Figure 264-1 Ring forms of *Plasmodium falciparum* within two erythrocytes (*center*).

suppression. The human host response to *Plasmodium* species infection includes natural immune mechanisms that prevent infection by other *Plasmodium* species, such as those of birds or rodents, as well as several alterations in erythrocyte physiology that prevent or modify malarial infection. Erythrocytes containing hemoglobin S (sickle erythrocytes) resist malaria parasite growth, erythrocytes lacking Duffy blood group antigen are resistant to *P. vivax*, and erythrocytes containing hemoglobin F (fetal hemoglobin) and ovalocytes are resistant to *P. falciparum*. In hyperendemic areas, newborns rarely become ill with malaria, in part owing to passive maternal antibody and high levels of fetal hemoglobin. Children 3 mo to 2–5 yr of age have little specific immunity to malaria species and therefore suffer yearly attacks of debilitating and potentially fatal disease. Immunity is subsequently acquired, and severe cases of malaria become less common. Severe disease may occur during pregnancy or after extended residence outside the endemic region. In general, extracellular *Plasmodium* organisms are targeted by antibody, whereas intracellular organisms are targeted by cellular defenses such as T lymphocytes, macrophages, polymorphonuclear leukocytes, and the spleen.

Clinical Manifestations.

Children and adults are asymptomatic during the initial phase, the **incubation period** of malaria infection. The usual incubation periods follow: *P. falciparum*, 9–14 days; *P. vivax,* 12–17 days; *P. ovale*, 16–18 days, and *P. malariae*, 18–40 days. The incubation period can be prolonged for any *Plasmodium* species in patients with partial immunity or incomplete chemoprophylaxis and as long as 6–12 mo for *P. vivax*. A prodrome lasting 2–3 days is noted in some patients before parasites are detected in the blood. Prodromal symptoms include headache, fatigue, anorexia, myalgia, slight fever, and pain in the chest, abdomen, or joints.

The classic presentation of malaria, seldom noted with other infectious diseases, consists of **paroxysms** of fever alternating with periods of fatigue but otherwise relative wellness. Symptoms associated with febrile paroxysms include high fever, rigors, sweats, and headache, as well as myalgia, back pain, abdominal pain,

nausea, vomiting, diarrhea, pallor, and jaundice. Paroxysms coincide with the rupture of schizonts that occurs every 48?hr with *P. vivax* and *P. ovale* and results in daily fever spikes and every 72?hr with *P. malariae* resulting in every other or every third day fever spikes. Periodicity is less apparent with *P. falciparum* and mixed infections. Patients with primary infection, such as travelers from nonendemic regions, also may have irregular symptomatic episodes for 2–3 days before regular paroxysms begin. Children with malaria often have special clinical features that differ from those of adults. In children older than 2 mo of age who are nonimmune, symptoms of malaria vary widely from low-grade fever and headache to a temperature greater than 104°F with headache, drowsiness, anorexia, nausea, vomiting, diarrhea, pallor, cyanosis, splenomegaly, hepatomegaly, anemia, thrombocytopenia, a normal or low leukocyte count, or any combination of these manifestations.

Recrudescence after a primary attack may occur from the survival of erythrocyte forms in the bloodstream. Long-term relapse is caused by release of merozoites from an exoerythrocytic source in the liver (*P. vivax* and *P. ovale*) or persistence within the erythrocyte (*P. malariae*). A history of typical symptoms in a person more than a few weeks after return from an endemic area therefore indicates *P. vivax*, *P. ovale*, or *P. malariae* infection.

P. falciparum is the most severe form of malaria and is associated with more intense parasitemia. Fatality rates of up to 25% in nonimmune adults and 30% in nonimmune infants may occur if appropriate therapy is not instituted promptly. For this reason, *the diagnosis of P. falciparum malaria constitutes a medical emergency*. Malaria caused by *P. ovale, P. vivax,* and *P. malariae* usually result in parasitemias of less than 2%. Malaria caused by *P. falciparum,* however, can reach 60% or more because *P. ovale* and *P. vivax* primarily infect immature erythrocytes, *P. malariae* infects only mature erythrocytes, while *P. falciparum* infects immature and mature erythrocytes. *P. falciparum* is most commonly associated with serious complications, although milder or asymptomatic infections occur in those who are partially immune.

P. vivax malaria generally is less severe than *P. falciparum* malaria but may cause death from ruptured spleen or in association with reticulocytosis after anemia. Relapse of *P. vivax* malaria may occur if antihepatic malaria treatment is not given and is common within 6 mo after an acute attack but may occur as long as 5 yr after initial infection.

P. malariae is the mildest and most chronic of all malaria infections. Recrudescence has been observed 30–50 yr after an acute attack. Although parasitemia is often low, untreated *P. malariae* can cause chronic ill health in addition to acute febrile illness.

P. ovale malaria is the least common type of malaria. It is similar to *P. vivax* malaria and commonly is found in conjunction with *P. falciparum* malaria.

Congenital malaria (malaria acquired from the mother prenatally or perinatally) is a serious problem in tropical areas but is rarely reported in the United States. In endemic areas, congenital malaria is an important cause of abortions, miscarriages, stillbirths, premature births, intrauterine growth retardation, and neonatal deaths. Congenital malaria usually occurs in a nonimmune mother with *P. vivax* or *P. malariae*, although it can be observed with any of the human malaria species. The first sign or symptom most commonly occurs between 10–30 days of age (range, 14?hr to several months of age). Signs and symptoms include fever, restlessness, drowsiness, pallor, jaundice, poor feeding, vomiting, diarrhea, cyanosis, and hepatosplenomegaly. Malaria is often severe during pregnancy and may have an adverse effect on the fetus or neonate owing to maternal illness or placental infection even in the absence of transmission from mother to child.

Diagnosis.

Any child who presents with fever or unexplained systemic illness and has traveled or had residence in a malaria-endemic area within the previous year should be assumed to have life-threatening malaria until proven otherwise. Malaria illness should be considered regardless of the use of chemoprophylaxis. Important criteria that suggest *P. falciparum* malaria include symptoms occurring less than 1 mo after return from an endemic area, intense parasitemia (>2%), ring forms with double chromatin dots, and erythrocytes infected with more than one parasite.

The diagnosis of malaria is established by identification of organisms on Giemsa-stained smears of peripheral blood. Giemsa stain is superior to Wright stain or Leishman stain. Both thick and thin blood smears should be examined. The concentration of erythrocytes on a thick smear is 20–40 times that on a thin smear and is used to quickly scan large numbers of erythrocytes. The thin smear allows for positive identification of the malaria species and determination of the percentage of infected erythrocytes. The latter is useful in following the response to therapy. Identification of the species is best made by an experienced microscopist and checked against color plates of the various *Plasmodium* species. Although *P. falciparum* is most likely to be identified from blood just after a febrile paroxysm, the timing of the smears is less important than their being obtained several times a day over a period of 3 successive days. A single negative blood smear does not exclude malaria; it may be necessary to repeat the smears as often as every 4–6?hr a day to make a diagnosis. Most symptomatic patients with malaria will have detectable parasites on thick blood smears within a 48-hr period. It is important to realize that in nonimmune persons symptoms typically occur 1–2 days before parasites are detectable on blood smear. A new monoclonal antibody test that is incorporated

in a test strip for fingerprick blood samples is as sensitive as a thick smear for detection of *P. falciparum*. Polymerase chain reaction is even more sensitive but technically more complex.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis of malaria is broad and includes viral infections such as influenza and hepatitis, sepsis, pneumonia, meningitis, encephalitis, endocarditis, gastroenteritis, pyelonephritis, babesiosis, brucellosis, leptospirosis, tuberculosis, relapsing fever, typhoid fever, yellow fever, amebic liver abscess, Hodgkin disease, and collagen vascular disease.

Treatment.

Physicians caring for patients with malaria or traveling to endemic areas need to be aware of current information regarding malaria because the problem of resistance to antimalarial drugs is ongoing and has greatly complicated therapy and prophylaxis. The best source for such information is the CDC Malaria Hotline, which is available to physicians 24?hr a day (770-488-7788 from 8:00 am to 4:30 pm EST and 404-639-2888 from 4:30 pm to 8:00 am EST weekends and holidays). Fever without an obvious cause in any patient who has left a *P. falciparum*– endemic area within the incubation period of 9–14 days and is nonimmune should be considered a medical emergency. Thick and thin blood smears should immediately be obtained and, if positive, the patient should be hospitalized and begun on therapy. If blood films are negative, they should be repeated every few hours; but if the patient is severely ill, antimalarial therapy should be initiated immediately.

P. FALCIPARUM MALARIA.

Malaria acquired in *P. falciparum* areas with known chloroquine resistance or where there is any doubt about chloroquine sensitivity after checking the CDC Malaria Hotline should generally be treated with drugs other than chloroquine (Table 264–1). Intravenous quinidine or quinine* should be administered for patients who cannot retain oral fluids and medication because of vomiting; have neurologic dysfunction, pulmonary edema, or renal failure; have a peripheral asexual parasitemia more than 5%; or have a peripheral asexual parasitemia of 1–4% with a severe attack. Such patients should be admitted to the intensive care unit for electrocardiographic monitoring to detect arrhythmias, widening QRS complex, or prolonged QT interval. Patients also should be monitored for hypotension and other complications and for plasma quinidine levels. Parenteral therapy should be continued until the parasitemia is less than 1%, which usually occurs within 48?hr, and/or until oral medication can be tolerated. Quinine sulfate (30?mg/kg/24?hr PO in 3 doses) is then given for a total of 3 days of combined quinidine/quinine therapy, with completion of therapy by either tetracycline 6.25?mg/kg PO qid for 7 days or Fansidar (25?mg pyrimethamine and 500?mg sulfadoxine per tablet) in one oral dose (¼–3 tablets according to age) on the last day of therapy. Use of Fansidar is contraindicated in patients with a history of sulfonamide or pyrimethamine intolerance, in infants younger than 2 mo of age, and in pregnant women at term.

Patients with mild to moderate infection, parasitemia less than 5%, and any doubt about chloroquine sensitivity should be given oral quinine sulfate (30?mg/kg/24?hr in 3 doses) for 3–7 days with an additional antimalarial drug consisting of any one of the following: a single treatment dose of Fansidar on the last day of quinine; doxycycline or tetracycline qid for 7 days; or clindamycin for 5 days. Alternatives to these regimens include mefloquine given in two doses 12?hr apart, atovaquone and proguanil (Malarone) for 3 days, or atovaquone and doxycycline for 3 days (see Table 264–1). Exceptions to the just mentioned regimens include quinine treatment for 7 consecutive days for patients who acquire *P. falciparum* in Thailand and the avoidance of Fansidar for patients who acquire *P. falciparum* infections in Thailand, Burma, Cambodia, or the Amazon basin. Mefloquine is contraindicated for use in patients with a known hypersensitivity to mefloquine or with a history of epilepsy or severe psychiatric disorders. Mefloquine may be administered to persons concurrently receiving ß–blockers if they have no underlying arrhythmia; however, mefloquine is not recommended for persons with cardiac conduction abnormalities. Quinidine or quinine may exacerbate the known side effects of mefloquine; patients not responding to mefloquine therapy or failing mefloquine prophylaxis should be monitored closely if they are treated with quinidine or quinine.

Patients with uncomplicated *P. falciparum* malaria acquired in areas without chloroquine resistance should be treated with oral chloroquine; however, if the parasite count does not drop rapidly (within 24–48?hr) and become negative after 4 days, chloroquine resistance should be assumed and the patient begun on a different antimalarial drug. Supportive therapy is very important and includes red blood cell transfusion(s) to maintain the hematocrit more than 20%, exchange transfusion in life-threatening *P. falciparum* malaria with parasitemia more than 5%, supplemental oxygen and ventilatory support for pulmonary edema or cerebral malaria, careful intravenous rehydration for severe malaria, intravenous glucose for hypoglycemia, anticonvulsants for cerebral malaria with seizures, and dialysis for renal failure. Corticosteroids are no longer recommended for cerebral malaria.

P. VIVAX, P. OVALE, OR *P. MALARIAE* MALARIA.

If malaria was acquired in areas where *P. falciparum* is not endemic, the treatment is with chloroquine even though a few rare cases of chloroquine-resistant *P. vivax* malaria have been described from Indonesia and New Guinea. Clinical and blood smear response to therapy should be monitored. If vomiting precludes oral administration, chloroquine can be given by nasogastric tube, or, in rare cases and with great care, by intramuscular administration. Sudden death has been attributed to parenteral administration of chloroquine to children. Intravenous quinidine or quinine is given in severe cases. Patients with *P. vivax* or *P. ovale* malaria should be given primaquine once daily for 14 days to prevent relapse. Some strains may require two courses of primaquine. Patients given primaquine must be checked for glucose-6-phosphate dehydrogenase deficiency before initiation of the drug because it can cause hemolytic anemia in such patients. Patients with malaria of any type need to be monitored for possible recrudescence with repeat blood smears at the end of therapy because recrudescence may occur 90 or more days after therapy with low-grade resistant organisms. For children living in endemic areas, mothers should be encouraged to treat fever with an antimalarial drug. If such children are severely ill, they should be given the same therapy as nonimmune children.

Complications.

Cerebral malaria is a serious complication of *P. falciparum* infection that is especially common in children and nonimmune adults. Cerebral malaria is associated with a fatality rate of 20–40% but rarely causes long-term sequelae if it is treated appropriately. It usually develops after the patient has been ill for several days but may develop precipitously. As with other complications, cerebral malaria is more likely in patients with parasitemia greater than 5%. The symptoms always include decreased level of consciousness and range in severity from drowsiness and severe headache to confusion, delirium, hallucinations, or deep coma. Physical findings may be normal or may include fever to 106–108°F, seizures, muscular twitching, rhythmic movement of the head or extremities, contracted or unequal pupils, retinal hemorrhages, hemiplegia, absent or exaggerated deep tendon reflexes, and a positive Babinski sign. Lumbar puncture reveals increased pressure and cerebrospinal fluid protein with minimal or no pleocytosis and a normal glucose concentration. There are no specific electroencephalographic findings with cerebral

malaria.

TABLE 264-1 -- **Treatment of Malaria in Children**

Drug[*]	Dosage
***All Plasmodium Species Except Chloroquine-Resistant* Plasmodium falciparum**	
Oral Drug of Choice	
Chloroquine phosphate	10?mg base/kg (maximum: 600?mg base) then 5?mg base/kg (maximum: 300?mg base), 6 hr later, and 5?mg base/kg/24 hr (maximum: 300?mg base) at 24 and 48 hr
Parenteral Drug of Choice	
Quinidine gluconate	10?mg/kg loading dose (maximum: 600?mg) over 1–2 hr, then 0.02?mg/kg/min continuous infusion until oral therapy can be started
or	
Quinine dihydrochloride (not available in the USA)	20?mg/kg loading dose over 4 hr, then 10?mg/kg over 2–4 hr q8h (maximum: 1,800?mg/24 hr) until oral therapy can be started
P. falciparum *Acquired in Areas of Known Chloroquine Resistance*	
Oral Regimen of Choice	
Quinine sulfate[†]	30?mg/kg/24 hr divided in three doses for 3–7 days (maximum: 650?mg/dose)
plus	
Tetracycline[‡]	20?mg/kg/24 hr divided in four doses for 7 days (maximum: 250?mg/dose)
or plus	
Pyrimethamine-sulfadoxine (Fansidar)[§]	<1 yr, single dose of 1/4 tablet 1–3 yr, single dose of 1/2 tablet 4–8 yr, single dose of 1 tablet 9–14 yr, single dose of 2 tablets >14 yr, single dose of 3 tablets
or	
Mefloquine hydrochloride	15?mg PO followed by 10?mg/kg PO 8–12 hours later (maximum: 1,250?mg) for 1 day
Parenteral	
Quinidine gluconate	Same as for chloroquine-sensitive *P. falciparum*
or	
Quinine dihydrochloride	Same as for chloroquine-sensitive *P. falciparum*
Prevention of Relapses:* Plasmodium vivax *and* Plasmodium ovale *Only	
Primaquine phosphate[¶]	0.3?mg base/kg/24 hr for 14 days (maximum: 15?mg base [26.3?mg salt])

** Review contraindications and adverse effects before use (see text).*
† For treatment of P. falciparum *infections acquired in Southeast Asia, and possibly in other areas including South America, quinine sulfate should be continued for 7 days.*
‡ Physicians must weigh the benefits of tetracycline therapy against the possibility of dental staining in children younger than 8 yr of age.
§ Fansidar (25?mg pyrimethamine and 500?mg sulfadoxine per tablet) should not be used for treatment of malaria acquired in Southeast Asia and the Amazon basin because of possible resistance. Carry a single dose for treatment of febrile illness when medical care is not immediately available.
Mefloquine is not licensed by the U.S. Food and Drug Administration (FDA) for children who weigh less than 15 kg, but recent Centers for Disease Control and Prevention (CDC) recommendations allow use of the drug to be considered in children without weight restrictions when travel to chloroquine-resistant P. falciparum *areas cannot be avoided. For most patients, 15?mg/kg (maximum: 750?mg) in a single dose is effective therapy, except for those who acquired infection in the areas of the Amazon basin, or the Thailand-Cambodia and Thailand-Myanmar borders. If the 25?mg/kg/24 hr dose is used, 15?mg/kg (maximum: 750?mg) is given followed 8–12 hr later by 10?mg/kg (maximum: 500?mg).*
¶ Primaquine phosphate can cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. A G6PD screening test should be performed before intiating treatment. Pregnant women should not be administered primaquine.

Renal failure is a common complication of severe *P. falciparum* malaria. It results from deposition of hemoglobin in renal tubules, decreased renal blood flow, and acute tubular necrosis. **Blackwater fever** is a clinical syndrome that consists of severe hemolysis, hemoglobinuria, and renal failure. It is a rare complication that occurs when the combination of antibody directed against parasite-laden erythrocytes and complement result in severe hemolytic anemia, hemoglobinuria, oliguria, and jaundice. Renal failure usually requires peritoneal dialysis or hemodialysis.

Pulmonary edema may occur several days after therapy has begun and is commonly associated with excessive intravenous therapy. It can develop rapidly and may be fatal. Thus, great care should be taken not to overhydrate patients with *P. falciparum* malaria.

Hypoglycemia is a complication of malaria that is more common in children, pregnant women, and patients receiving quinine therapy. Patients may have a decreased level of consciousness that can be confused with cerebral malaria. Hypoglycemia is associated with increased mortality and neurologic sequelae.

Thrombocytopenia is a common complication of *P. falciparum* and *P. vivax* malaria. Although significant bleeding is uncommon without DIC, platelet counts can decrease to 10,000–20,000/mm^3 .

Splenic rupture is a rare complication that may occur with acute infection owing to any malaria species. Splenic rupture can occur spontaneously but is usually the result of trauma that includes overly vigorous palpation on physical examination. It causes severe internal hemorrhage and may result in death if removal of the spleen and blood transfusion are not performed in a timely manner.

Algid malaria is a rare form of *P. falciparum* malaria that occurs with overwhelming infection, hypotension, hypothermia, rapid weak pulse, shallow breathing, pallor, and vascular collapse. Death may occur within a few hours.

Prevention.

Malaria prevention consists of reducing exposure to infected mosquitoes and chemoprophylaxis. The most accurate and current information on areas in the world where malaria risk and drug resistance exist can be obtained by contacting local and state health departments or the Centers for Disease Control and Prevention or consulting the United States Public Health Service's annual publication *Health Information for International Travel.*

Travelers to endemic areas should remain in well-screened areas from dusk to dawn when the risk of transmission is highest. They should sleep under permethrin-treated mosquito netting and spray insecticides indoors at sundown. During the day the travelers should wear clothing that covers the arms and legs with trousers tucked into shoes or boots. Mosquito repellent

should be applied to thin clothing and exposed areas of the skin with repeated applications every 1–2?hr. A child should not be taken outside from dusk to dawn but, if absolutely necessary, diethyltoluamide (DEET) in a 10–15% solution should be applied to exposed areas except for the eyes, mouth, or hands (hands are often placed in the mouth). The DEET should then be washed off as soon as the child comes back inside. Adverse reactions to DEET include rashes, toxic encephalopathy, and seizures. Even with these precautions, a child should be taken to a physician immediately if the child develops illness when traveling to a malarious area.

Chemoprophylaxis is necessary for all visitors to and residents of the tropics who have not lived there since infancy (see Table 285–2). Children of nonimmune women should have chemoprophylaxis from birth. Chemoprophylaxis should be started 1–2 wk before entering the endemic area (except for doxycycline administration, which can begin 1–2 days before departure) and continue for at least 4 wk after leaving. Chloroquine is given in the few remaining areas of the world free of chloroquine-resistant malaria strains (as of January 1992, Hispaniola, Central America north of Panama, and the Middle East). In areas where chloroquine-resistant *P. falciparum* exists, chemoprophylaxis is complicated. Children who travel to areas where chloroquine-resistant strains are transmitted should be given mefloquine. An alternative regimen should be given to children if they have a known hypersensitivity to mefloquine, are receiving cardiotropic drugs, especially ß-blockers, or have a history of convulsive or certain psychiatric disorders. Such children should be given chloroquine. In addition, if they weigh more than 30 pounds, they should bring Fansidar tablets to be taken if fever develops and medical care is not available within 24?hr. An alternative combination that could be considered for sulfa-sensitive individuals older than 8 yr of age is chloroquine and, in place of Fansidar, doxycycline. Doxycycline is equivalent to mefloquine for short-term prophylaxis, but for long-term prophylaxis doxycycline is not as good because of side effects associated with its long-term use. There have been several reports of both mefloquine and Fansidar resistance. The combination of atovaquone and proguanil (Malarone) has been approved for prophylaxis of malaria in areas where chloroquine resistance exists, although dosing is uncertain in children who weigh less than 30 pounds. Finally, extensive efforts have been made to develop a malaria vaccine but results to date have been disappointing.

Chapter 265 - Babesiosis (*Babesia*)

Peter J. Krause

Babesiosis is an emerging malaria-like disease caused by an intraerythrocytic protozoan that is transmitted by ticks. The clinical manifestations of babesiosis range from subclinical illness to fulminant disease resulting in death.

Etiology.

The causative protozoan was first described in cattle in 1891 by the Hungarian microbiologist Babes. Since then, more than 90 species of *Babesia* have been described that infect a wide variety of wild and domestic animals throughout the world.

The primary reservoir for *Babesia microti* is the white-footed mouse *(Peromyscus leucopus),* and the primary vector is the deer tick (*I. dammini*, also known as *I. scapularis*). Deer ticks also transmit the etiologic agents of Lyme disease and human granulocytic ehrlichiosis and may simultaneously transmit both microorganisms. Deer (*Odocoileus virginianus*) serve as the host on which adult ticks most abundantly feed but are incompetent reservoirs.

Epidemiology.

Since the first documented case of human babesial infection was reported in 1957, infection by *B. divergens* has been demonstrated in Europe and infection by *B. microti* has become endemic in the northeastern and upper midwestern United States. A parasite very closely related to *B. gibsoni* (WA-1) appears to infect humans along the Pacific coast, whereas another that is closely related to *B. divergens* (MO-1) has been reported in Missouri. Human babesiosis cases also have been documented in Asia and Africa.

Rarely, babesiosis is acquired through blood transfusions or by transplacental transmission.

Pathogenesis.

Erythrocyte lysis is responsible for many of the clinical manifestations and complications of the disease, including fever, hemolytic anemia, jaundice, hemoglobinemia, hemoglobinuria, and renal insufficiency. Obstruction of blood vessels by parasitized erythrocytes causes ischemia and necrosis that may result in splenomegaly, hepatomegaly and hepatic dysfunction, and cerebral abnormalities. The spleen has an important role in clearing parasitemia along with antibody, T and B cells, complement, cytokines, macrophages, and polymorphonuclear leukocytes. Immunity is sometimes incomplete because low-level parasitemia may exist for as long as 26 mo after symptoms have resolved and recrudescence may occur.

Clinical Manifestations.

The clinical severity of babesiosis ranges from subclinical infection to fulminating disease resulting in death. Although infection is common in endemic areas, many are mild or asymptomatic. In some highly endemic areas, moderate to severe disease is frequently observed. Nantucket Island reported 21 cases in 1994, which translates to 280 cases/ 100,000 population, placing the community burden of disease in a category with gonorrhea as “moderately common.” The case fatality rate was estimated at 5% in a retrospective study of 136 New York cases. Thus, in certain sites, in certain years of high transmission, babesiosis may constitute a significant public health burden.

There is often no recollection of a tick bite because the unengorged *I. dammini* nymph is only about 2?mm long. In clinically apparent cases, symptoms of babesiosis begin after an incubation period of 1–9 wk from the beginning of tick feeding or 6–9 wk after transfusion. Typical symptoms in moderate to severe infection include intermittent temperature to as high as 40°C (104°F) and one or more of the following: chills, sweats, myalgia, arthralgia, nausea, and vomiting. Less commonly noted are emotional lability, hyperesthesia, headache, sore throat, abdominal pain, conjunctival injection, photophobia, weight loss, and nonproductive cough. The findings on physical examination generally are minimal, often consisting only of fever. Mild splenomegaly, hepatomegaly, or both are noted occasionally but rash seldom is reported. Abnormal laboratory findings include moderately severe hemolytic anemia, an elevated reticulocyte count, thrombocytopenia, proteinuria, and elevated blood urea nitrogen and creatinine levels. The leukocyte count is normal to slightly decreased, with a “left shift.” Babesiosis usually lasts for a few weeks to several months, with prolonged recovery of up to 18 mo in severe cases.

Patients at increased risk for severe disease include those who lack a spleen, are on immunosuppressive drugs, are infected with *B. divergens*, are older than age 40 yr, or with concomitant HIV infection or Lyme disease. Concurrent babesiosis and Lyme disease infection occurs in approximately 15% of patients experiencing Lyme disease in parts of southern New England and results in more severe illness than with either disease alone. Moderate to severe babesiosis may occur in children, but infection generally is less severe than in adults. Several cases of neonatal babesiosis have been described. Neonates usually are infected from blood transfusion and may develop severe illness.

Diagnosis.

Diagnosis of *B. microti* infection in human hosts is made by microscopic demonstration of the organism using Giemsa-stained thin blood films. Parasitemias may be exceedingly sparse, especially early in the course of illness. Thick blood smears may be used, but the organisms appear as simple chromatin dots that might be mistaken for stain precipitate or iron inclusion bodies. Subinoculation of a sample of patient's blood into hamsters or gerbils or in vitro cultivation are too specialized for all but the most experienced laboratories. The polymerase chain reaction (PCR) is a sensitive and specific test for detection of *Babesia* DNA that should supplant the hamster inoculation test. Serologic testing is useful, particularly in diagnosing *B. microti* infection. The indirect immunofluorescence serologic assay (for both IgG and IgM antibodies) is sensitive and specific and may quickly confirm a diagnosis of babesiosis when parasites are scarce or not detectable.

Treatment.

The combination of clindamycin (20–40?mg/kg/day divided tid PO) and quinine (25?mg/kg/day divided tid PO) for 7 to 10 days is the therapy of choice for babesiosis in children. Adverse reactions are common, however, especially tinnitus and abdominal distress. In addition, treatment failures have been reported, particularly in patients with HIV infection. The combination of atovaquone (40?mg/kg/day divided bid PO) and azithromycin (12?mg/kg/day as a single dose PO) is an alternative antibabesial combination that has been shown in adults to be as effective as clindamycin and quinine but with fewer adverse effects. Exchange blood transfusion can decrease parasitemia rapidly and remove toxic by-products of babesial infection but should be reserved for patients with severe infections.

Prevention.

Prevention of babesiosis can be accomplished by avoiding areas where ticks, deer, and mice are known to thrive. Use of clothing that covers the lower part of the body and that is sprayed or impregnated with diethyltoluamide (DEET), dimethyl phthalate, or permethrin (Permanone) is recommended for those who travel in the foliage of endemic areas. A search for ticks on people and pets should be carried out and the ticks removed using tweezers to grasp the mouth parts without squeezing the body of the tick.

Prospective blood donors with a history of babesiosis are excluded from giving blood to prevent transfusion-related cases.

Chapter 266 - Toxoplasmosis *(Toxoplasma gondii)*

Rima McLeod
Jack S. Remington

Toxoplasma gondii, an obligate intracellular protozoan, is acquired perorally, transplacentally, or, rarely, parenterally in laboratory accidents; by transfusion; or from a transplanted organ. In immunologically normal children, acute acquired infection may be asymptomatic, cause lymphadenopathy, or damage almost any organ. Once acquired, latent encysted organisms persist for the lifetime of the host. In immunocompromised infants or children, either initial acquisition or recrudescence of latent organisms often causes signs or symptoms related to the central nervous system (CNS). Infection acquired congenitally, if untreated, almost always causes signs or symptoms in the perinatal period or later in life. The most frequent of these signs are due to chorioretinitis and CNS lesions. However, other manifestations, such as intrauterine growth retardation, fever, lymphadenopathy, rash, hearing loss, pneumonitis, hepatitis, and thrombocytopenia, also occur. Congenital toxoplasmosis in infants with HIV infection may be fulminant.

Etiology.

T. gondii is a coccidian protozoan that multiplies only in living cells. The tachyzoites are oval or crescent-like, measuring 2–4 × 4–7?µm. Tissue cysts, which are 10–100?µm in diameter, may contain thousands of parasites and remain in tissues, especially the CNS and skeletal and heart muscle, for the life of the host. *Toxoplasma* can multiply in all tissues of mammals and birds.

Newly infected cats and other Felidae excrete infectious *Toxoplasma* oocysts in their feces. *Toxoplasma* are acquired by susceptible cats by ingestion of infected meat containing encysted bradyzoites or by ingestion of oocysts excreted by other recently infected cats. The parasites then multiply through schizogonic and gametogonic cycles in the distal ileal epithelium of the cat intestine. Oocysts containing two sporocysts are excreted, and, under proper conditions of temperature and moisture, each sporocyst matures into four sporozoites. For about 2 wk the cat excretes 10^5–10^7 oocysts/day, which, in a suitable environment, may retain their viability for more than 1 yr. Oocysts sporulate 1–5 days after excretion and are then infectious. Oocysts are killed by drying, boiling, and exposure to some strong chemicals, but not to bleach. Oocysts have been isolated from soil and sand frequented by cats, and outbreaks associated with contaminated water have been reported. Oocysts and tissue cysts are sources of animal and human infections (Fig. 266–1). There are three clonal types of *T. gondii* that have different virulence for mice (and perhaps for humans) and different capacity to form large numbers of cysts.

Epidemiology.

Toxoplasma infection is ubiquitous in animals and is one of the most common latent infections of humans throughout the world. Incidence varies considerably among people and animals in different geographic areas. In many areas of the world, approximately 5.35% of pork, 9–60% of lamb, and 0–9% of beef contain *T. gondii* organisms. Significant antibody titers have been detected in 50–80% of residents of some localities and in less than 5% in others. A higher prevalence of infection usually occurs in warmer, more humid climates.

Figure 266-1 Life cycle of *Toxoplasma gondii* and prevention of toxoplasmosis by interruption of transmission to humans.

Human infection is usually acquired by the oral route by eating undercooked or raw meat that contains cysts or by ingestion of oocysts. Freezing meat to -20°C or heating it to 66°C renders the cysts noninfectious. Outbreaks of acute acquired infection have occurred in families who have consumed the same infected food. Except for transplacental infection from mother to fetus and, rarely, by organ transplantation or transfusion, *Toxoplasma* organisms are not transmitted from person to person.

Seronegative transplant recipients who receive an organ (e.g., heart or kidney) from seropositive donors have experienced life-threatening illness requiring therapy. Seropositive recipients may have increased serologic titers without associated disease.

CONGENITAL TOXOPLASMOSIS.

Transmission to the fetus usually occurs when infection is acquired by an immunologically normal mother during gestation. Congenital transmission from immunologically normal women infected before pregnancy is

extremely rare. Immunocompromised women who are chronically infected have transmitted the infection to their fetuses. The incidence of congenital infection in the United States ranges from 1/1,000 to 1/8,000 live births. The incidence of newly acquired infection in a population of pregnant women depends on the risk of becoming infected in that specific geographic area and the proportion of the population that has not been previously infected.

Pathogenesis.

T. gondii is usually acquired by children and adults from ingesting food that contains cysts or that is contaminated with oocysts usually from acutely infected cats. Oocysts also may be transported to food by flies and cockroaches. When the organism is ingested, bradyzoites are released from cysts or sporozoites from oocysts, and organisms then enter gastrointestinal cells. They multiply, rupture cells, and infect contiguous cells. They are transported through lymphatics and disseminated hematogenously throughout the body. Tachyzoites proliferate, producing necrotic foci surrounded by a cellular reaction. With development of a normal immune response (humoral and cell-mediated), tachyzoites disappear from tissues. In immunodeficient individuals and some apparently immunologically normal patients, acute infection progresses and may cause potentially lethal involvement such as pneumonitis, myocarditis, or necrotizing encephalitis.

In acute acquired toxoplasmosis, characteristic lymph node changes include reactive follicular hyperplasia with irregular clusters of epithelioid histiocytes that encroach on and blur margins of germinal centers. Focal distention of sinuses with monocytoid cells also occurs.

Cysts form as early as 7 days after infection and remain for the life span of the host. During latent infection they produce little or no inflammatory response but cause recrudescent disease in immunocompromised patients or chorioretinitis in older children who acquired infection congenitally.

CONGENITAL TOXOPLASMOSIS.

When a mother acquires infection during gestation, organisms may disseminate hematogenously to the placenta. When this occurs, infection may be transmitted to the fetus transplacentally or during vaginal delivery. Of untreated maternal infections acquired in the first trimester, approximately 17% of fetuses are infected, usually with severe disease. Of untreated maternal infection acquired in the third trimester, approximately 65% of fetuses are infected, usually with disease that is mild or inapparent at birth. These different rates of transmission and outcomes are most likely related to placental blood flow, virulence and amount of *T. gondii* acquired, and immunologic capacity of the mother to limit parasitemia.

Examination of the placenta of infected newborns may reveal chronic inflammation and cysts. Tachyzoites can be seen with Wright or Giemsa stains but are best demonstrated with immunoperoxidase technique. Tissue cysts stain well with periodic acid– Schiff (PAS) and silver stains as well as with immunoperoxidase technique. Gross or microscopic areas of necrosis may be present in many tissues, especially CNS, choroid and retina, heart, lungs, skeletal muscle, liver, and spleen. Areas of calcification occur in brain.

Almost all congenitally infected individuals manifest signs or symptoms of infection, such as chorioretinitis, by adolescence if they are not treated in the newborn period. Some severely involved infants with congenital infection appear to have *Toxoplasma* antigen–specific anergy of their lymphocytes, which may be important in pathogenesis of their disease. Predilection to predominant involvement of the CNS and eye in congenital infection has not been fully explained.

IMMUNITY.

There are profound and prolonged alterations of T-lymphocyte populations during acute acquired *T. gondii* infections, but they have not correlated with outcome. Lymphocytosis, increased CD8 count, and decreased CD4:CD8 ratio are commonly present. Depletion of CD4 cells in patients with AIDS may contribute to severe manifestations of toxoplasmosis seen in these patients.

Clinical Manifestations.

Manifestations of primary infection with *T. gondii* are highly variable and influenced primarily by host immunocompetence. Reactivation of previously asymptomatic congenital toxoplasmosis is usually manifest as ocular toxoplasmosis.

ACQUIRED TOXOPLASMOSIS.

Immunologically normal children who acquire infection postnatally may have no clinically recognizable disease. When clinical manifestations are apparent, they may include almost any combination of fever, stiff neck, myalgia, arthralgia, maculopapular rash that spares the palms and soles, localized or generalized lymphadenopathy, hepatomegaly, hepatitis, reactive lymphocytosis, meningitis, brain abscess, encephalitis, confusion, malaise, pneumonia, polymyositis, pericarditis, pericardial effusion, and myocarditis. Chorioretinitis, usually unilateral, occurs in approximately 1% of cases. In Erecim, Brazil, an unusually high incidence of presumed toxoplasmic chorioretinitis, believed to be associated with acute acquired infection, has been described. Eighteen percent of the 80% of the population who have serum antibodies indicating they are infected with *T. gondii* have retinal lesions consistent with *T. gondii* chorioretinitis or scars. Two additional series of cases have been reported, one in France and one in Victoria, British Columbia, clearly documenting toxoplasmic chorioretinitis as part of the acute acquired infection. Symptoms may be present for a few days only or may persist many months. The most common manifestation is enlargement of one or a few lymph nodes in the cervical region. Cases of *Toxoplasma* lymphadenopathy rarely resemble infectious mononucleosis (due to Epstein-Barr virus or cytomegalovirus), Hodgkin disease, or other lymphadenopathies (see Chapter 482). In the pectoral area in older girls and women, the nodes may be confused with breast neoplasms. Mediastinal, mesenteric, and retroperitoneal lymph nodes may be involved. Involvement of intra-abdominal lymph nodes may be associated with fever and mimic appendicitis. Nodes may be tender but do not suppurate. Lymphadenopathy may appear and disappear for as long as 1–2 yr.

Most patients with malaise and lymphadenopathy recover spontaneously without antimicrobial therapy. Significant organ involvement in immunologically normal individuals is uncommon; however, some individuals have suffered significant morbidity (e.g., with rare instances of encephalitis, brain abscesses, hepatitis, myocarditis, pericarditis, or polymyositis).

OCULAR TOXOPLASMOSIS.

In the United States and Western Europe, *T. gondii* has been estimated to cause 35% of cases of chorioretinitis (Fig. 266–2). In Brazil, retinal lesions with the appearance of toxoplasmic chorioretinitis have occurred in multiple members of the same family. Retinal lesions are present in 18% of those who are seropositive for *T. gondii* infection in Erecim, Brazil. Manifestations include blurred vision, photophobia, epiphora, and, with macular involvement, loss of central vision. Findings due to congenital ocular toxoplasmosis also include strabismus, microphthalmia, microcornea, cataract, anisometropia, and nystagmus. Episodic recurrences are common, but precipitating factors have not been defined.

IMMUNOCOMPROMISED PERSONS.

Congenital *T. gondii* infection in infants with AIDS is usually a fulminant, rapidly fatal disorder, involving brain and other organs such as the lung and heart. Disseminated *T. gondii* infections also occur in older children who are immunocompromised by AIDS, by malignancies and cytotoxic therapy or corticosteroids, or by immunosuppressive drugs given for organ transplantation. Immunocompromised individuals experience the clinical forms of *Toxoplasma* infection that occur in immunologically normal individuals. Signs and symptoms that are referable to the CNS are the most frequent manifestations of severe disease (occurring in 50% of patients),

Figure 266-2 Toxoplasmic chorioretinitis. *A,* Active acute lesion by indirect ophthalmoscopy. *B,* The healed foci of toxoplasmic chorioretinitis may resemble a colobomatous defect (macular pseudocoloboma). (*B,* adapted from Desmonts G, Remington J: Congenital toxoplasmosis. In Remington JS, Klein JO [editors]: *Infectious Diseases of the Fetus and Newborn Infant,* 5th ed. Philadelphia, WB Saunders, 2001.)

although other organs also may be involved, including the heart, gastrointestinal tract, and testes.

Bone marrow transplant recipients present a special problem because active infection in these patients is difficult to diagnose. After transplantation, specific antibody level may remain the same, increase, or decrease and can become negative. Active infection often is fulminant and rapidly fatal.

Individuals who have antibodies to *T. gondii* and HIV infection are at significant risk of development of toxoplasmic encephalitis, which may be the presenting manifestation of AIDS. Although HAART and trimethoprim-sulfamethoxazole prophylaxis have diminished the incidence of toxoplasmosis in patients with HIV infection, toxoplasmic encephalitis remains the presenting manifestation in 20% of patients with AIDS. In patients with AIDS, toxoplasmic encephalitis is fatal if not treated. Typical findings of CNS toxoplasmosis in patients with AIDS include fever, headache, altered mental status, psychosis, cognitive impairment, seizures and focal neurologic defects, including hemiparesis, aphasia, ataxia, visual field loss, cranial nerve palsies, and dysmetria or movement disorders. Uncommon findings of CNS involvement include meningismus, panhypopituitarism, and the syndrome of inappropriate secretion of antidiuretic hormone. In adult patients with AIDS, toxoplasmic retinal lesions are often large with diffuse necrosis and contain many organisms but little inflammatory cellular infiltrate.

Toxoplasmic encephalitis and congenital toxoplasmosis are a particular problem in immunocompromised individuals from areas where the incidence of latent infection is high. From 25–50% of patients with AIDS and *Toxoplasma* antibodies ultimately experience toxoplasmic encephalitis in the absence of prophylaxis with trimethoprim-sulfamethoxazole and treatment of HIV infection with protease inhibitors. The reason why only a subpopulation of latently infected individuals experiences toxoplasmic encephalitis is unknown. A diagnosis of presumptive toxoplasmic encephalitis in patients with AIDS should prompt a therapeutic trial of medications effective against *T. gondii*. Clear clinical improvement within 7–14 days and improvement in findings of neuroradiologic studies within 3 wk after therapy is initiated make the presumptive diagnosis almost certain.

CONGENITAL TOXOPLASMOSIS.

The signs and symptoms associated with acute acquired *T. gondii* infection in the pregnant woman are the same as those seen in the immunologically normal child, most commonly lymphadenopathy. Most often, the acute acquired infection occurs without recognized symptoms or signs. Congenital infection also may be transmitted by an asymptomatic immunocompromised woman (e.g., those treated with corticosteroids and those with HIV infection).

Genetics. In monozygotic twins the clinical pattern of involvement is most often similar, whereas in dizygotic twins manifestations often differ. In dizygotic twins severe manifestations in one twin have led to a diagnosis of subclinical disease in the other twin. Also, congenital infection has occurred in only one twin of a pair of dizygotic twins. The major histocompatibility complex (MHC) class II gene DQ3 appears to be more frequent in patients seropositive for *T. gondii* infection with AIDS and toxoplasmic encephalitis than in patients seropositive for *T. gondii* infection with AIDS who do not have toxoplasmic encephalitis, and in children with congenital toxoplasmosis and hydrocephalus as compared with those without hydrocephalus. There were no children who were homozygous for the HLA-DQ3 allele with hydrocephalous, in contrast to the expected prevalence of homozygosity for this allele. This finding suggests that presence of HLA-DQ3 might be particularly detrimental to the fetus when toxoplasmosis is transmitted early in gestation.

Spectrum and Frequency of Signs and Symptoms. Congenital infection may present as a mild or severe neonatal disease, with onset during the 1st mo of life, or with sequelae or relapse of a previously undiagnosed infection at any time during infancy or later in life. A wide variety of manifestations of congenital infection occur in the perinatal period. These range from relatively mild signs, such as small size for gestational age, prematurity, peripheral retinal scars, persistent jaundice, mild thrombocytopenia, and cerebrospinal fluid pleocytosis, to the classic triad of signs consisting of chorioretinitis, hydrocephalus, and cerebral calcifications. Infection may result in erythroblastosis, hydrops fetalis, and perinatal death. More than half of

congenitally infected infants are considered normal in the perinatal period, but almost all such children will have ocular involvement later in life. Neurologic signs in neonates, which include convulsions, setting-sun sign, and an increase in head circumference due to hydrocephalus, may be associated with substantial cerebral damage. However, such signs also may occur in association with encephalitis without extensive destruction or with relatively mild inflammation adjacent to and obstructing the aqueduct of Sylvius. If such infants are treated promptly, signs and symptoms may resolve, and they may develop normally.

The spectrum and frequency of manifestations that develop in the perinatal period in infants with congenital *Toxoplasma* infection are presented in Table 266–1 . Infection in most of these 210 infants was initially suspected because their mothers were identified by a serologic screening program that detected pregnant women with acute acquired *T. gondii* infection. Twenty-one infants (10%) had severe congenital toxoplasmosis with CNS involvement, eye lesions, and general systemic manifestations. Seventy-one (34%) had mild involvement with normal clinical examination results other than retinal scars or isolated intracranial calcifications. In 116 (55%) there were no detectable manifestations; this may reflect the difficulties associated with funduscopic examination of the peripheral retina in infants and young children. These numbers represent an underestimation of the relative frequency of severe congenital infection for several reasons: the most severe cases, including most of those individuals who died, were not referred; therapeutic abortion was often performed when acute acquired infection of the mother was diagnosed early during pregnancy; in utero spiramycin therapy may have diminished the severity of infection; and only 13 infants had CT brain scans and 23% did not have a cerebrospinal fluid examination. Routine newborn examinations often yield normal findings for congenitally infected infants, but more careful evaluations may reveal significant abnormalities: specifically, of

TABLE 266-1 -- Signs and Symptoms in 210 Infants with Proved Congenital Toxoplasma Infection*

Finding	No. Examined	No. Positive (%)

Data adapted from Couvreur J, Desmonts G, Tournier G, et al: A homogeneous series of 210 cases of congenital toxoplasmosis in 0–11 mo old infants detected prospectively. Ann Pediatr (Paris) 1984;31:815–9.

* *Infants were identified by prospective study of infants born to women who acquired* Toxoplasma gondii *infection during pregnancy.*

28 infants who were detected by a universal state mandated serologic screening program for *T. gondii*–specific immunoglobulin M (IgM), 26 had normal findings on routine newborn examinations and 14 had significant abnormalities detected with more careful evaluation. These abnormalities included retinal scars (7 infants), active chorioretinitis (3 infants), and CNS abnormalities (8 infants).

There is a wide clinical spectrum of untreated congenital toxoplasmosis that is

clinically apparent in the first year of life (Table 266–2). More than 80% of these children had an IQ of less than 70, and many had convulsions and severely impaired vision.

Skin. Cutaneous manifestations in infants with congenital toxoplasmosis include rashes, petechiae, ecchymoses, or large hemorrhages secondary to thrombocytopenia. Rashes may be fine punctate, diffuse maculopapular, lenticular, deep blue-red, sharply defined macular, and diffuse blue and papular. Macular rashes involving the entire body, including the palms and soles; exfoliative dermatitis; and cutaneous calcifications have been described. Jaundice due to hepatic involvement with *T. gondii* and/or hemolysis, cyanosis due to interstitial pneumonitis from congenital infection, and edema secondary to myocarditis or nephrotic syndrome may be present. Jaundice and conjugated hyperbilirubinemia may persist for months.

Systemic Signs. From 25% to more than 50% of infants with clinically apparent disease at birth are born prematurely. Low Apgar scores also are common. Intrauterine growth retardation and instability of temperature regulation may occur. Other systemic manifestations include lymphadenopathy, hepatosplenomegaly, myocarditis, pneumonitis, nephrotic syndrome, vomiting, diarrhea, and feeding problems. Bands of metaphyseal lucency and irregularity of the line of provisional calcification at the epiphyseal plate may occur without periosteal reaction in the ribs, femurs, and vertebrae. Congenital toxoplasmosis may be confused with isosensitization causing erythroblastosis fetalis; the Coombs test result is usually negative with congenital *T. gondii* infection.

Endocrine Abnormalities. Endocrine abnormalities may occur secondary to hypothalamic or pituitary involvement or

Adapted from Eichenwald H: A study of congenital toxoplasmosis. In Siim JC (editor): Human Toxoplasmosis. Copenhagen, Munksgaard, 1960, pp 41–49. Study performed in 1947. The most severely involved institutionalized patients were not included in the later study of 101 children.

**Patients with otherwise undiagnosed central nervous system disease in the 1st yr of life.*
† Patients with otherwise undiagnosed non-neurologic diseases during the first 2 mo of life.

end-organ involvement. Reported endocrinopathies include myxedema, persistent hypernatremia with vasopressin-sensitive diabetes insipidus without polyuria or polydipsia, sexual precocity, and partial anterior hypopituitarism.

Central Nervous System. Neurologic manifestations of congenital toxoplasmosis vary from massive acute encephalopathy to subtle neurologic syndromes. Toxoplasmosis should be considered as a cause of any undiagnosed neurologic disease in children younger than 1 yr of age, especially if retinal lesions are present.

Hydrocephalus may be the sole clinical neurologic manifestation of congenital toxoplasmosis and may either be compensated or require shunt placement. Hydrocephalus may present in the perinatal period, progress after the perinatal period, or, less commonly, present later in life. Patterns of seizures are protean and have included focal motor seizures, petit and grand mal seizures, muscular twitching, opisthotonus, and hypsarrhythmia (which may resolve with corticotropin [ACTH] therapy). Spinal or bulbar involvement may be manifested by paralysis of the extremities, difficulty in swallowing, and respiratory

distress. Microcephaly usually reflects severe brain damage, but some children with microcephaly caused by congenital toxoplasmosis who have been treated appear to function normally in the early years of life. Untreated congenital toxoplasmosis that is symptomatic in the 1st yr of life can cause substantial diminution in cognitive function and developmental delays. Intellectual impairment also occurs in some children with subclinical infection despite treatment with pyrimethamine and sulfonamides. Seizures and focal motor defects may become apparent after the newborn period, even when infection is subclinical at birth.

Cerebrospinal fluid (CSF) abnormalities occur in at least one third of infants with congenital toxoplasmosis. Local production of *T. gondii*–specific antibodies may be demonstrated in CSF of congenitally infected individuals. CT of the brain with contrast

Figure 266-3 Head CT scans of infants with congenital toxoplasmosis. *A,* CT scan at birth that has areas of hypolucency, mildly dilated ventricles, and small calcifications. *B,* CT scan of the same child at 1 yr of age (after antimicrobial therapy for 1 yr). This scan is normal with the exception of two small calcifications. This child's Mental Development Index (MDI) at 1 yr of age was 140 by the Bayley Scale of Infant Development. *C,* CT scan from a 1-yr-old infant who was normal at birth. His meningoencephalitis became symptomatic in the 1st weeks of life but was not diagnosed correctly and remained untreated during his 1st 3 mo of life. At 3 mo of age, development of hydrocephalus and bilateral macular chorioretinitis led to the diagnosis of congenital toxoplasmosis, and antimicrobial therapy was initiated. This scan shows significant residual atrophy and calcifications. This child has substantial motor dysfunction, development delays, and visual impairment. *D,* CT scan obtained during the 1st mo of life of a microcephalic child. Note the numerous calcifications. This child's IQs (i.e., using the Stanford-Binet Intelligence Scale for children when she was 3 yr old and the Wechsler Preschool and Primary Scale Intelligence when she was 5 yr old) were 100 and 102, respectively. She received antimicrobial therapy during her 1st yr of life. *E,* CT scan with hydrocephalus owing to aqueductal stenosis (before shunt). *F,* Scan from the same patient as the scan in *E,* after shunt. This child's IQ (i.e., using the Stanford-Binet Intelligence Scale for children) was approximately 100 when she was 3 and 6 yr old. (Adapted from McAuley J, Boyer K, Patel D, et al: Early and longitudinal evaluations of treated infants and children and untreated historical patients with congenital toxoplasmosis: The Chicago Collaborative Treatment Trial. *Clin Infect Dis* 1994;18:38–72.)

medium enhancement is useful to detect calcifications, determine ventricular size, image active inflammatory lesions, and demonstrate porencephalic cystic structures (Fig. 266–3). Calcifications occur throughout the brain, but there appears to be a special propensity for development of such lesions in the caudate nucleus (i.e., especially basal ganglia area), choroid plexus, and subependyma. Ultrasonography may be useful for following ventricular size in congenitally infected infants. MRI, enhanced CT, and radionuclide brain scans may be useful for detecting active inflammatory lesions.

Eyes. Almost all untreated congenitally infected individuals will develop chorioretinal lesions by adulthood, and about 50% will have severe visual impairment. *T. gondii* causes a focal necrotizing retinitis in congenitally infected individuals (see Fig. 266–2). Retinal detachment may occur. Any part of the retina

may be involved, either unilaterally or bilaterally, including the maculae. The optic nerve may be involved, and toxoplasmic lesions that involve projections of the visual pathways in the brain or the visual cortex also may lead to visual impairment. In association with retinal lesions and vitritis, the anterior uvea may be intensely inflamed, leading to erythema of the external eye. Other ocular findings include cells and protein in the anterior chamber, large keratic precipitates, posterior synechiae, nodules on the iris, and neovascular formation on the surface of the iris, sometimes with an associated increase in intraocular pressure and development of glaucoma. The extraocular musculature may also be involved directly. Other manifestations include strabismus, nystagmus, visual impairment, and microphthalmia. The differential diagnosis of lesions resembling those of ocular toxoplasmosis includes congenital colobomatous defect and other inflammatory lesions due to cytomegalovirus, *Treponema pallidum, Mycobacterium tuberculosis,* or vasculitis. Ocular toxoplasmosis is a recurrent and progressive disease that requires multiple courses of therapy. There are limited data that suggest that occurrence of lesions in the early years of life may be prevented by instituting antimicrobial treatment (with pyrimethamine and sulfonamides in alternate months with spiramycin) during the 1st yr of life and that treatment of the infected fetus in utero followed by treatment in the 1st yr of life with pyrimethamine, sulfadiazine, and leukovorin reduces the incidence

and the severity of the retinal disease.

Ears. Sensorineural hearing loss, both mild and severe, may occur. It is not known whether this is a static or progressive disorder. Treatment in the 1st yr of life is associated with diminished occurrence of this sequela.

Concomitant Infections. Congenital toxoplasmosis in infants with HIV infection usually presents as a severe and fulminant illness with substantial CNS involvement but also may be more indolent in its presentation with focal neurologic deficits or systemic manifestations such as pneumonitis.

Diagnosis.

Diagnosis of acute *Toxoplasma* infection can be established by isolation of *T. gondii* from blood or body fluids and also by demonstration of tachyzoites in sections or preparations of tissues and body fluids, cysts in the placenta or tissues of a fetus or newborn, and characteristic lymph node histologic features. Serologic tests also are very useful for diagnosis.

CULTURE.

Organisms are isolated by inoculation of body fluids, leukocytes, or tissue specimens into mice or tissue cultures. Body fluids should be processed and inoculated immediately, but *T. gondii* has been isolated from tissues and blood that have been stored at 4°C overnight. Freezing or treatment of specimens with formalin kills *T. gondii*. From 6–10 days after inoculation into mice, or earlier if mice die, peritoneal fluids should be examined for tachyzoites. If they survive for 6 wk and there is antibody in sera of the inoculated mouse, definitive diagnosis is made by visualization of *Toxoplasma* cysts in mouse brain. If cysts are not seen, subinoculations of mouse tissue into other mice are performed.

Microscopic examination of tissue culture inoculated with *T. gondii* shows necrotic, heavily infected cells with numerous extracellular tachyzoites. Isolation of *T. gondii* from blood or body fluids reflects acute infection. Except in the fetus or neonate it is usually not possible to distinguish acute from past infection by isolation of *T. gondii* from tissues such as skeletal muscle, lung, brain, or eye obtained by biopsy or at autopsy.

Diagnosis of acute infection can be established by demonstration of tachyzoites in biopsy tissue sections, bone marrow aspirate, or body fluids such as CSF or amniotic fluid. Immunofluorescent antibody and immunoperoxidase staining techniques may be necessary because it is often difficult to see the tachyzoite with ordinary stains. Tissue cysts are diagnostic of infection but do not differentiate between acute and chronic infection; the presence of many cysts suggests recent acute infection. Cysts in the placenta or tissues of the newborn infant establish the diagnosis of congenital infection. Characteristic histologic features strongly suggest the diagnosis of toxoplasmic lymphadenitis.

SEROLOGIC TESTING.

Multiple serologic tests may be necessary to confirm the diagnosis of congenital or acutely acquired *Toxoplasma* infection. Each laboratory that reports serologic test results must have established values for their tests that diagnose infection in specific clinical settings, provide interpretation of their results, and ensure appropriate quality control before therapy is based on serologic test results. Serologic test results used as the basis for therapy should be confirmed in a reference laboratory.

The **Sabin-Feldman dye test** is sensitive and specific. It measures primarily IgG antibodies. Results should be expressed in international units (IU/mL), based on international standard reference sera available from the World Health Organization.

The **IgG indirect fluorescent-antibody (IgG-IFA) test** measures the same antibodies as the dye test, and the titers tend to be parallel. These antibodies usually appear 1–2 wk after infection, reach high titers (=1:1,000) after 6–8 wk, and then decline over months to years. Low titers (1:4–1:64) usually persist for life. Antibody titer does not correlate with severity of illness. Approximately half of the commercially available IFA kits for *T. gondii* have been found to be improperly standardized and may yield significant numbers of false-positive and false-negative results.

An **agglutination test** (Bio-Mérieux, Lyon, France) that is available commercially in Europe uses formalin-preserved whole parasites to detect IgM antibodies. This test is accurate, simple to perform, and inexpensive.

The **IgM indirect fluorescent antibody (IgM-IFA) test** is useful for the diagnosis of acute infection with *T. gondii* in the older child because IgM antibodies appear earlier (often by 5 days after infection) and disappear sooner than IgG antibodies. In most instances, antibodies detected by the test rise rapidly (to levels of 1:50 to <1:1,000) and fall to low titers (1:10 or 1:20) or disappear after weeks or months. However, some patients continue to have positive results at low titers for as long as several years. The IgM-IFA test detects *Toxoplasma*-specific IgM in only approximately 25% of congenitally infected infants at birth. IgM antibodies also are often not present in sera of immunodeficient patients with acute toxoplasmosis or in most patients with active toxoplasmosis present only in the eye. The IgM-IFA test may yield false-positive results as a result of rheumatoid factor.

The **double-sandwich enzyme-linked immunosorbent assay (ELISA)** is more sensitive and specific than the IgM-IFA test for detection of *Toxoplasma* IgM antibodies. In the older child, a level of IgM antibodies against *Toxoplasma* in serum of 2.0 or greater (value of one reference laboratory; each laboratory must establish its own values) indicates that *Toxoplasma* infection has most likely been acquired recently. The IgM-ELISA detects approximately 75% of infants with congenital infection. IgM-ELISA avoids both the false-positive results from rheumatoid factor and false-negative results from high levels of passively transferred maternal IgG antibody in fetal serum, as occurs in the IgM-IFA test. Results obtained with commercial kits must be interpreted with caution because false-positive reactions are not infrequent. Care must also be taken to determine whether kits have been standardized for diagnosis of infection in specific clinical settings (e.g., in the newborn infant). The **IgA-ELISA** is a more sensitive test than the IgM ELISA for detection of congenital infection in the fetus and newborn as well as for detection of

acute infection in some pregnant women.

The **immunosorbent agglutination assay (ISAGA)** combines trapping of a patient's IgM to a solid surface and use of formalin-fixed organisms or antigen-coated latex particles. It is read as an agglutination test. There are no false-positive results

from rheumatoid factor or antinuclear antibodies. IgM antibodies to *Toxoplasma* are detected by the IgM-IFA test for a shorter time than they are by the IgM-ELISA. The IgM-ISAGA is more sensitive than the IgM-ELISA and may detect specific IgM antibodies before and for longer periods than the IgM-ELISA. At present, IgM-ISAGA is the best test for diagnosis of congenital infection in the newborn. The IgE-ELISA and IgE-ISAGA are also useful in establishing the diagnosis of congenital toxoplasmosis or acute acquired *T. gondii* infection.

The **differential agglutination test (HS/SC)** compares antibody titers obtained with formalin-fixed tachyzoites **(HS antigen)** with titers obtained using acetone- or methanol-fixed tachyzoites **(AC antigen)** to differentiate recent and remote infections in adults and older children. This method may be particularly useful in differentiating remote infection in pregnant women, because levels of IgM and IgA antibodies detectable by ELISA or ISAGA may remain elevated for prolonged periods (e.g., months to years in adults and older children).

The **avidity test** can be used to determine whether acute infection began more than 12–16 wk earlier (high avidity test result).

The **indirect hemagglutination (IHA) test** measures different *T. gondii* antibodies from those measured in IFA and dye tests. They may persist for years. However, the IHA test should not be used in infants with suspected congenital infection or in screening for infection acquired during pregnancy because it may be negative for too long a period early during infection.

A relatively higher level of *Toxoplasma* antibody in the aqueous humor or in cerebrospinal fluid demonstrates local production of antibody during active ocular or CNS toxoplasmosis. This comparison is calculated as follows:

Significant correlation coefficients [C] are more than or equal to 8 for ocular infection, more than or equal to 4 for CNS for congenital infection, and more than 1 for CNS infection in patients with AIDS. If the serum dye test titer is more than or equal to 300?IU/mL, most often it is not possible to demonstrate significant local antibody production using this formula with either the dye test or the IgM-IFA test titer. IgM antibody may be present in CSF.

Toxoplasma antigen has been detected during acute *Toxoplasma* infection but not in sera of uninfected or chronically infected individuals. Antigen was present in the serum, amniotic fluid, and CSF in the few infants tested with congenital infections.

Comparative **Western immunoblot** tests of sera from a mother and infant may detect congenital infection. Infection is suspected when the mother's serum and her infant's serum contain antibodies that react with different *Toxoplasma* antigens.

Enzyme-linked immunofiltration assay (ELIFA), using micropore membranes, permits simultaneous study of antibody specificity by immunoprecipitation and characterization of antibody isotypes by immunofiltration with enzyme-labeled antibodies. This method may be capable of detecting 85% of cases of congenital infection in the first few days of life. It is still being evaluated.

Polymerase chain reaction (PCR) is used to amplify the DNA of *T. gondii,* which then can be detected by using a DNA probe. Detection of a repetitive *T. gondii* gene, the *B1* gene, in amniotic fluid is the procedure of choice for establishing the diagnosis of congenital *Toxoplasma* infection in the fetus. Sensitivity and specificity of this test using amniotic fluid obtained at 18 wk of gestation or later are approximately 95%. Before and after that time, PCR is less sensitive for detection of congenital infection. PCR of vitreous fluid has been used to diagnose ocular toxoplasmosis. PCR of peripheral white blood cells, CSF, and urine has detected congenital infection.

Lymphocyte blastogenesis to *Toxoplasma* antigens has been used to diagnose congenital toxoplasmosis if a question persists concerning the diagnosis and other test results are negative. However, a negative result does not exclude the diagnosis, because many infected infants do not respond to *T. gondii* antigens in the newborn period.

ACQUIRED TOXOPLASMOSIS.

Recent infection is diagnosed by seroconversion from a negative to a positive IgG antibody titer (in the absence of transfer of antibody by transfusion); a serial two-tube rise in *Toxoplasma*-specific IgG titer when sera are obtained 3 wk apart and tested in parallel; or the presence of *Toxoplasma*-specific IgM antibody.

OCULAR TOXOPLASMOSIS.

IgG antibody titers of 1:4 to 1:64 are usual in older children with active toxoplasmic chorioretinitis. When the retinal lesions are characteristic and serologic tests findings are positive, the diagnosis is likely. PCR of vitreous fluid has been used to diagnose ocular toxoplasmosis but is infrequently performed because of risks associated with obtaining vitreous fluid.

IMMUNOCOMPROMISED PERSONS.

IgG antibody titers may be low, and *Toxoplasma*-specific IgM is often absent in immunocompromised patients with toxoplasmosis. Demonstration of *Toxoplasma* antigens or DNA in serum, blood, and CSF may identify disseminated *Toxoplasma* infection in immunocompromised persons.

Resolution of CNS lesions during a therapeutic trial of pyrimethamine and sulfadiazine has been useful in patients with AIDS. Brain biopsy has been used to establish the diagnosis of toxoplasmic encephalitis when there is no response to this

therapeutic trial or to exclude other likely diagnoses.

CONGENITAL TOXOPLASMOSIS.

Fetal ultrasound examination, performed every 2 wk during gestation, and PCR analysis of amniotic fluid are used for prenatal diagnosis. *T. gondii* may also be isolated from the placenta.

Serologic tests are the most useful in establishing a diagnosis of congenital toxoplasmosis. Either persistent or rising titers in the dye or IFA test or a positive IgM ELISA or ISAGA result is diagnostic of congenital toxoplasmosis. The half-life of IgM is 3–5 days, so if there is a placental leak, the level of IgM antibodies in the infant's serum decreases significantly within 1–2 wk. Passively transferred maternal IgG antibodies may require many months to a year to disappear from the infant's serum, depending on the magnitude of the original titer. Synthesis of *Toxoplasma* antibody is usually demonstrable by the 3rd mo of life if the infant is untreated. If the infant is treated, synthesis may be delayed until the 9th mo of life, and, infrequently, it may not occur at all. When an infant begins to synthesize antibody, infection may be documented serologically even without demonstration of IgM antibodies by an increase in the ratio of specific serum antibody titer to the total IgG, whereas the ratio will decrease if the specific antibody has been passively transferred from the mother.

At birth, when a diagnosis of congenital toxoplasmosis is suspected, the following diagnostic studies should be performed: general, ophthalmologic, and neurologic examinations; head CT scan; attempt to isolate *T. gondii* from placenta and infant's leukocytes from umbilical cord blood and buffy coat; measurement of serum *Toxoplasma*-specific IgG, IgM, IgA, and IgE antibodies and the total amount of IgM and IgG in serum; lumbar puncture including analysis of CSF for cells, glucose, protein, *Toxoplasma*-specific IgG and IgM antibodies, and total amount of IgG; and evaluations of CSF for *T. gondii* by PCR and inoculation into mice. Presence of *Toxoplasma*-specific IgM in CSF that is not contaminated with blood or local antibody production of Toxoplasma-specific IgG antibody demonstrated in CSF establishes the diagnosis of congenital *Toxoplasma* infection.

Many manifestations similar to those of congenital toxoplasmosis occur in other perinatal diseases, especially disease caused by cytomegalovirus. Neither cerebral calcification nor chorioretinitis is pathognomonic. Fewer than 50% of children younger than 5 yr of age with chorioretinitis satisfy the serologic criteria for congenital toxoplasmosis; the causes of most of the other cases are unknown. The clinical picture in the newborn infant may also be compatible with sepsis, aseptic meningitis, syphilis, or hemolytic disease.

Treatment.

Pyrimethamine plus sulfadiazine or trisulfapyrimidines act synergistically against *Toxoplasma*. Combined therapy is indicated to treat many of the forms of toxoplasmosis. However, use of pyrimethamine is contraindicated during the 1st trimester of pregnancy. Spiramycin should be used to prevent transmission of infection to the fetus of acutely infected pregnant women and to treat congenital toxoplasmosis. Pyrimethamine inhibits the enzyme dihydrofolate reductase (DHFR), and thus the synthesis of folic acid, and therefore produces a dose-related, reversible, and usually gradual depression of the bone marrow, resulting in thrombocytopenia, leukopenia, and anemia. Neutropenia is the most common side effect in treated infants. All patients treated with pyrimethamine should have platelet and leukocyte counts twice weekly. Seizures may occur with overdosage of pyrimethamine. Folinic acid (calcium leukovorin) should always be administered concomitantly with pyrimethamine to prevent suppression of the bone marrow. Potential toxic effects of sulfonamides (e.g., crystalluria, hematuria, and rash) should be monitored. Hypersensitivity reactions occur, especially in patients with AIDS.

ACQUIRED TOXOPLASMOSIS.

Patients with lymphadenopathy do not need specific treatment unless they have severe and persistent symptoms or evidence of damage to vital organs. If such signs and symptoms occur, treatment with pyrimethamine, sulfadiazine, and leukovorin should be initiated. Patients who appear to be immunologically normal but have severe and persistent symptoms or damage to vital organs (e.g., chorioretinitis, myocarditis) need specific therapy until these specific symptoms resolve, followed by therapy for an additional 2 wk. This therapy usually lasts for at least 4–6 wk; the optimal duration of therapy is unknown. A loading dose of pyrimethamine for older children is 2?mg/kg/24?hr (maximum: 50?mg/24?hr), given for the first 2 days of treatment. The maintenance dose is 1?mg/kg/24?hr (maximum: 50?mg/24?hr). Folinic acid is administered orally at a dosage of 5–20?mg three times a week (or even daily depending on the leukocyte count). Sulfadiazine or trisulfapyrimidine is administered to children older than 1 yr of age at a dosage of 100?mg/kg/24?hr (maximum: 4?g/24?hr).

OCULAR TOXOPLASMOSIS.

Patients with ocular toxoplasmosis are usually treated with pyrimethamine, sulfadiazine, and leukovorin for approximately 1 wk after the lesion develops a quiescent appearance (i.e., sharp borders and associated inflammatory cells in the vitreous resolve), which usually occurs in 2–4 wk. Within 7–10 days the borders of the retinal lesions sharpen, and visual acuity usually returns to that noted before development of the acute lesion. Systemic corticosteroids have been administered concomitantly with antimicrobial treatment when lesions involve the macula, optic nerve head, or papillomacular bundle. Most new lesions appear contiguous to old ones). Occasionally, vitrectomy and removal of the lens are needed to restore visual acuity.

IMMUNOCOMPROMISED PERSONS.

Serologic evidence of acute infection in an immunocompromised patient, regardless of whether signs and symptoms of infection are present or tachyzoites are present in tissue, are indications for therapy similar to that described for immunocompetent children with symptoms of organ injury. It is important to establish the diagnosis as rapidly as possible and institute treatment early. In immunocompromised patients other than those with AIDS, therapy should be continued for at least 4–6 wk beyond

complete resolution of all signs and symptoms of active disease. Careful follow-up observation of these patients is imperative because relapse may occur, requiring prompt reinstitution of therapy. Relapse is frequent in patients with AIDS, and suppressive therapy with pyrimethamine and sulfonamides traditionally has been continued for life. One study suggests that it may be possible to discontinue maintenance therapy when the CD4 count has remained at more than 200 cells/µL for 4–6 mo and all lesions have resolved. Therapy usually induces a beneficial response clinically, but it does not eradicate cysts. Treatment of patients with AIDS and *T. gondii* seropositively should be continued as long as CD4 counts remain at less than 200 cells/µL. Prophylactic treatment with trimethoprim-sulfamethoxazole for *Pneumocystis carinii* pneumonia appears to reduce the incidence of toxoplasmosis in patients with AIDS.

CONGENITAL TOXOPLASMOSIS.

All infected newborns should be treated, whether or not they have clinical manifestations of the infection. In infants with congenital infection, treatment may be effective in interrupting acute disease that damages vital organs. Infants should be treated for 1 yr with oral pyrimethamine (2?mg/kg/24?hr for 2 days, then 1?mg/kg/24?hr for 2 or 6 mo, then 1?mg/kg/ given on Monday, Wednesday, and Friday), sulfadiazine or triple sulfonamides (100?mg/kg/24?hr divided bid), and calcium leukovorin (5–10?mg/kg/24?hr given on Monday, Wednesday, and Friday). In the U.S. National Collaborative Study, the relative efficacy in reducing sequelae of infection and the safety of treatment with 2 versus 6 mo of the higher dosage of pyrimethamine are being compared.[*] Pyrimethamine and sulfadiazine are available only in tablet form and can be prepared as suspensions. Prednisone (1?mg/kg/24?hr divided bid PO) has been utilized in addition when active chorioretinitis involves the macula or otherwise threatens vision or the CSF protein is 1,000?mg/dL or more at birth, but its efficacy also is not established.

PREGNANT WOMEN WITH T. GONDII INFECTION.

The immunologically normal pregnant woman who acquired *T. gondii* before conception does not need treatment to prevent congenital infection of her fetus. Although data are not available to allow for a definitive time interval, if infection occurs during the 6 mo prior to conception, it is reasonable to evaluate the fetus and treat to prevent congenital infection in the fetus in the same manner as described for the acutely infected pregnant patient.

Treatment of a pregnant woman who acquires infection at any time during pregnancy reduces the chance of congenital infection in her infant. The medications used are spiramycin[†] for prevention and pyrimethamine in combination with sulfadiazine when the fetus is found or it is highly likely to be infected. Because pyrimethamine is potentially teratogenic, spiramycin is administered in the 1st trimester. The dose of spiramycin is 1?g every 8?hr given without food; lower doses are less effective. Toxicity is infrequent. Adverse reactions include paresthesias, rash, nausea, vomiting, and diarrhea. Fetal infection is treated with pyrimethamine (50?mg once daily PO) and sulfadiazine (2?g bid PO). Leukovorin (10?mg once daily PO) is administered with pyrimethamine. Treatment of the mother of an infected fetus with pyrimethamine and sulfadiazine reduces infection in the placenta and the severity of disease in the newborn. Delay in maternal treatment during gestation results in more brain and eye disease in the infant. Diagnostic amniocentesis should not be limited to 17–18 wk gestation pregnancies when there is high suspicion that the fetus may be infected. Overall sensitivity of PCR with amniotic fluid is at 85%: sensitivity of PCR using amniotic fluid is less in early and late gestation than in mid gestation.

---

*Information concerning the U.S. National Collaborative Study evaluating these regimens can be obtained by calling 773-834-4152.
†Spiramycin is available in the United States through the FDA (telephone: 302-443-7580) when diagnosis of acute infection is confirmed in a reference laboratory (telephone: 650-326-8120).

The approach in France to congenital toxoplasmosis includes systematic serologic screening of all women of childbearing age and again intrapartum. Mothers with acute infection are treated with spiramycin, which decreases the transmission from 60% to 23%. Ultrasonography and amniocentesis for PCR at approximately 18 wk gestation are used for fetal diagnosis; they have 97% sensitivity and 100% specificity. Fetal infection is treated with pyrimethamine and sulfadiazine, or by termination of pregnancy. This strategy has an excellent outcome with normal development of children. Only 19% have subtle findings of congenital infection, including intracranial calcifications (13%) and chorioretinal scars (6%), although 39% have chorioretinal scars detected at follow-up observation during later childhood.

Chronically infected pregnant women who have been immunocompromised by cytotoxic drugs or corticosteroid therapy have transmitted *T. gondii* to their fetuses. Such women should be treated with spiramycin throughout gestation. The best approach to prevention of congenital toxoplasmosis in the fetus of a pregnant woman with HIV infection and inactive *T. gondii* infection is unknown. If the pregnancy is not terminated, the mother should be treated with spiramycin during the first 17 wk of gestation and then with pyrimethamine and sulfadiazine until term. In a study of adult patients with AIDS, pyrimethamine (75?mg/24?hr Po) combined with high dosages of intravenously administered clindamycin (1,200?mg every 6?hr IV) appeared equal in efficacy to sulfadiazine and pyrimethamine. Other currently experimental agents include the macrolides roxithromycin and azithromycin.

Prognosis.

Early institution of specific treatment for congenitally infected infants usually cures the manifestations of toxoplasmosis, including active chorioretinitis, meningitis, encephalitis, hepatitis, splenomegaly, and thrombocytopenia. Hydrocephalus due to aqueductal obstruction may develop or become worse during therapy. Such treatment also may reduce the incidence of some sequelae, such as diminished cognitive or abnormal motor function. Without therapy, chorioretinitis often recurs. Children with extensive involvement at birth may function normally later in life or have mild to severe impairment of vision, hearing, cognitive function, and other neurologic functions. Delays in diagnosis and therapy, perinatal hypoglycemia, hypoxia, hypotension, repeated shunt infections, and severe visual impairment are associated with a poorer prognosis. The prognosis is guarded but is not necessarily poor for infected babies. Treatment with pyrimethamine and sulfadiazine does not eradicate the encysted parasite. No protective vaccine is available.

Prevention.

Counseling pregnant women about the methods of preventing transmission of *T. gondii* (see Fig. 266–1) during pregnancy can substantially reduce acquisition of infection during gestation. Women who do not have specific antibody to *T. gondii* before pregnancy should only eat well-cooked meat during pregnancy and avoid contact with oocysts excreted by cats. Cats that are kept indoors, maintained on prepared food, and not fed fresh, uncooked meat should not contact encysted *T. gondii* or shed oocysts. Serologic screening, ultrasound monitoring, and treatment of pregnant women during gestation can also reduce the incidence and manifestations of congenital toxoplasmosis.

Chapter 267 - Pneumocystis carinii

Walter T. Hughes

Pneumocystis carinii pneumonia (interstitial plasma cell pneumonitis) in an immunocompromised host is a life-threatening infection. It is believed to result in part from activation of latent organisms acquired in early childhood, de novo infection acquired later in life, or both. Even in the most severe cases, with rare exceptions, the organisms and the disease remain localized to the lungs.

Etiology.

P. carinii is a common extracellular parasite found in the lungs of mammals worldwide. The taxonomic placement of this organism has not been established, but it has attributes of fungi and protozoa. Although *P. carinii* DNA has genomic homology closer to those of fungi, its morphologic features and susceptibility to drugs are similar to those of protozoa.

Epidemiology.

Serologic surveys show most humans become infected with *P. carinii* before 4 yr of age. In the healthy host, these infections are usually asymptomatic. *P. carinii* DNA can often be detected in nasopharyngeal aspirates of normal infants. Pneumonia caused by *P. carinii* occurs almost exclusively in severely immunocompromised hosts, including those with congenital or acquired immunodeficiency disorders or malignancies, and in organ transplant recipients.

Without prophylaxis, approximately 40% of infants and children and 70% of adults with AIDS, 12% of children with leukemia, and 10% of patients with organ transplants experience *P. carinii* pneumonia. Epidemics that occurred among debilitated infants in Europe during and after World War II have been attributed to malnutrition.

The natural habitat and mode of transmission to humans are unknown. Experiments in rats have demonstrated animal-to-animal transmission by the airborne route, but animal-to-human transmission is unlikely because of the host-specific nature of *P. carinii.* Person-to-person transmission has been suggested from a few studies but has not been conclusively demonstrated.

Pathogenesis.

Two forms of *P. carinii* are found in the alveolar spaces: cysts that are 5–8?µm in diameter and may contain up to eight pleomorphic intracystic sporozoites, and the extracystic trophozoites, which are 2–5?µm delicate cells derived from excysted sporozoites. *P. carinii* attaches to type I alveolar epithelial cells by adhesive proteins such as fibronectin and mannose-dependent ligand. Alveolar macrophages phagocytize and kill opsonized *P. carinii* organisms, releasing tumor necrosis factor. The inflammatory process is associated with disruption of surfactant function and respiratory impairment. The histopathologic features of *P. carinii* pneumonia are of two types. The first type is infantile interstitial plasma cell pneumonitis, which is seen in epidemic outbreaks in debilitated infants at 3–6 mo of age. Extensive infiltration with thickening of the alveolar septum occurs, and plasma cells are prominent. The second type is a diffuse desquamative alveolar disease found in immunocompromised children and adults. The alveoli contain large numbers of *P. carinii* in a foamy exudate with alveolar macrophages active in the phagocytosis of organisms. The alveolar septum is not infiltrated to the extent it is in the infantile type, and plasma cells are usually absent.

Cell-mediated immunity has the major role in defense against *P. carinii* pneumonia. This is evidenced by the high frequency of *P. carinii* pneumonia in severe combined immunodeficiency disorder, with attack rates greater than 40%, and the infrequency of its occurrence in X-linked agammaglobulinemia. Studies in patients with AIDS show an increase in the occurrence of *P. carinii* pneumonia in the presence of markedly decreased CD4 T-lymphocyte counts. The CD4 cell count provides a useful indicator in both older children and adults of the necessity of prophylaxis for *P. carinii* pneumonia.

Clinical Manifestations.

The epidemic infantile form of *P. carinii* interstitial plasma cell pneumonitis is seen predominantly in infants 3–6 mo of age. The onset of hypoxia and symptoms is subtle with tachypnea but without fever, progressing to intercostal, suprasternal, and infrasternal retractions, nasal flaring, and cyanosis. In the sporadic form of *P. carinii* pneumonia occurring in children and adults with underlying immunodeficiency, the onset of hypoxia and symptoms is usually abrupt with fever, tachypnea, dyspnea, and cough, progressing to nasal flaring and cyanosis. This latter type accounts for the majority of cases, although the severity of clinical expression may vary. Rales are usually not detected on physical examination.

The chest radiograph reveals bilateral diffuse alveolar disease with a granular pattern. The earliest densities are perihilar, and progression proceeds peripherally, sparing the apical areas until last.

Diagnosis.

A definitive diagnosis requires the demonstration of *P. carinii* in the lung in the presence of clinical signs and symptoms of the infection. Methods for obtaining appropriate specimens for detecting organisms include bronchoalveolar lavage, tracheal aspirate, transbronchial lung biopsy, bronchial brushings, percutaneous transthoracic needle aspiration, and open lung biopsy. Induced sputum samples are helpful if *P. carinii* is found, but the absence of the organisms in induced sputum does not exclude the infection. The open lung biopsy is the most reliable method, although bronchoalveolar lavage is more practical in most cases. Four stains are in general use: Grocott-Gomori stain and toluidine blue stain for the cyst form, polychrome stains such as Giemsa stain for the trophozoites and sporozoites, and the fluorescein-labeled monoclonal antibody stains for both trophozoites and cysts. Polymerase chain reaction analysis of respiratory specimens offers promise as a rapid diagnostic method, but a standardized system for clinical use has not been established.

Treatment.

The recommended therapy is trimethoprim-sulfamethoxazole (TMP-SMZ) (15–20?mg TMP, 75–100?mg SMZ/kg/ 24?hr divided qid) administered intravenously, or orally if there is mild disease and no malabsorption or diarrhea. The duration of treatment is about 3 wk for patients with AIDS and 2 wk for other patients. Unfortunately, adverse reactions frequently occur with trimethoprim-sulfamethoxazole, including rash and neutropenia in patients with AIDS but are less common in non–AIDS patients. For patients who cannot tolerate or fail to respond to trimethoprim-sulfamethoxazole after 5–7 days, pentamidine isethionate (4?mg/kg/24?hr as a single dose IV) may be used. Adverse reactions are frequent and include renal and hepatic dysfunction, hyperglycemia or hypoglycemia, rash, and thrombocytopenia. Atovaquone and trimetrexate glucuronate are alternative treatments that have been used primarily in adults with mild to moderate disease. Pharmacokinetic studies of atovaquone show that a dose of 30?mg/kg/24?hr divided bid PO for children 2 yr of age or older is adequate and safe; a dose of 45?mg/kg/24?hr divided bid PO is needed for children younger than 2 yr of age. Other effective therapies include combinations of trimethoprim plus dapsone and of clindamycin plus primaquine.

Some studies in adults suggest that administration of corticosteroids in addition to anti–*P. carinii* drugs increases the chances for survival in moderate and severe cases of *P. carinii* pneumonia. The recommended regimen of corticosteroids for adolescents older than 13 yr of age and for adults is oral prednisone, 80?mg/24?hr divided bid PO on days 1–5, 40?mg/24?hr once daily PO on days 6–10, and 20?mg/24?hr once daily PO on days 11–21. A regimen for children is oral prednisone, 2?mg/kg/24?hr for the first 7–10 days, followed by a tapering regimen for the next 10–14 days.

Complications.

Most complications occur as adverse events associated with the drugs used for treatment. Rarely, *P. carinii* infection affects extrapulmonary sites (e.g., retina, spleen, and bone marrow), but such infections are usually not symptomatic and also respond to treatment.

Prognosis.

Without treatment, *P. carinii* pneumonitis is fatal in almost all immunocompromised hosts within 3–4 wk of onset. The mortality rate is 10–30% if treatment is initiated early in the course of the pneumonia. Patients remain at risk for *P. carinii* pneumonia as long as they are immunocompromised. Continuous prophylaxis should be initiated or reinstituted at the end of therapy for patients with AIDS.

Prevention.

Patients at high risk for *P. carinii* pneumonia should be placed on chemoprophylaxis. Prophylaxis of infants born to HIV-infected mothers, and for HIV-infected infants and children, are based on age and CD4 cell counts (see Table 254–4). Patients with severe combined immunodeficiency syndrome, those with organ transplants, and those receiving intensive immunosuppressive therapy for cancer or other diseases are also candidates for prophylaxis. Trimethoprim-sulfamethoxazole (5?mg TMP, 25?mg SMZ/kg/24?hr once daily PO) is the drug of choice and may be given for 3 consecutive days each week, or, alternatively, each day. Alternatives for prophylaxis include dapsone (2?mg/kg/24?hr once daily PO; maximum: 100?mg/dose; or 4?mg/kg once weekly PO; maximum: 200?mg), atovaquone (30?mg/kg/24?hr once daily PO for 1–3 mo and infants older than 24 mo of age; 45?mg/kg/24?hr for infants 4–23 mo of age), and aerosolized pentamidine (300?mg monthly by Respirgard II nebulizer). The prophylaxis must be continued as long as the patient remains immunocompromised. Some AIDS patients who reconstitute adequate immune response during highly active antiretroviral therapy (HAART) may have prophylaxis withdrawn.

Section 13 - *Helminthic Diseases*

Chapter 268 - Ascariasis (*Ascaris lumbricoides*)

Sheral S. Patel
James W. Kazura

Etiology.

Ascariasis is caused by the nematode, or roundworm, *Ascaris lumbricoides*. Adult worms of *A. lumbricoides* inhabit the lumen of the small intestine and have a lifespan of 10–24 mo. The reproductive potential of *Ascaris* is prodigious in that a gravid female worms produces 200,000 eggs/24?hr. The fertile ova are oval in shape with a thick mammillated covering measuring 45–70?µm in length and 35–50?µm in breadth (Fig. 268–1). After passage in the feces, the eggs embryonate and become infective in 5–10 days under favorable environmental conditions.

Epidemiology.

Ascariasis occurs globally and is the most prevalent human helminthiasis in the world. It is most common in tropical areas of the world where environmental conditions are optimal for maturation of ova in the soil. Approximately 1 billion persons are estimated to be infected, with 4 million cases in the United States. Key factors linked with a higher prevalence of infection include poor socioeconomic conditions, use of human feces as fertilizer, and geophagia. Even though infection can occur at any age, the highest rate is in children of preschool or early school age. Transmission is primarily hand-to-mouth but may also involve ingestion of contaminated raw fruits and vegetables. Transmission is enhanced by the high output of eggs by fecund female worms and resistance of ova to the outside environment. *Ascaris* eggs can remain viable at 5–10°C for as long as 2 yr.

Pathogenesis.

Ascaris ova hatch in the small intestine after ingestion by the human host. Larvae are released, penetrate the intestinal wall, and migrate to the lungs by way of the venous circulation. The parasites then cause **pulmonary ascariasis** as they enter into the alveoli and migrate through the bronchi and trachea. They are subsequently swallowed and return to the intestines, where they mature into adult worms. Female *Ascaris* begin depositing eggs in 8–10 wk.

Figure 268-1 Fertilized (*A*) and unfertilized (*B, C*) eggs of *Ascaris lumbricoides* (×400). The egg illustrated in *C* may be mistaken for that of a different nematode or of a trematode.

Clinical Manifestations.

The clinical presentation depends on the intensity of infection and the organs involved. Most individuals have low to moderate worm burdens and have no symptoms or signs. The most common clinical problems are due to pulmonary disease and obstruction of the intestinal or biliary tract. Larvae migrating through these tissues may cause allergic symptoms, fever, urticaria, and granulomatous disease. The pulmonary manifestations resemble Löffler syndrome and include transient respiratory symptoms such as cough and dyspnea, pulmonary infiltrates, and blood eosinophilia. Larvae may be observed in the sputum. Vague abdominal complaints have been attributed to the presence of adult worms in the small intestine, although the precise contribution of the parasite to these symptoms is difficult to ascertain. A more serious complication occurs when a large mass of worms leads to acute bowel obstruction. Children with heavy infections may present with vomiting, abdominal distention, and cramps. In some cases, worms may be passed in the vomitus or stools. *Ascaris* worms occasionally migrate into the biliary and pancreatic ducts, where they cause cholecystitis or pancreatitis. Dead worms can serve as a nidus for stone formation. It is unclear whether infection with *A. lumbricoides* affects growth and nutrition. Some studies suggest that worm burden and poor growth status are independent, whereas others conclude that children with recurrent heavy infection are at risk of protein-energy malnutrition.

Diagnosis.

Microscopic examination of fecal smears can be used for diagnosis because of the high number of eggs excreted by adult female worms (see Fig. 268–1). A high index of suspicion in the appropriate clinical context is needed to diagnose pulmonary ascariasis or obstruction of the gastrointestinal tract.

Treatment.

Although several chemotherapeutic agents are effective against ascariasis, none have documented utility during the pulmonary phase of infection. Treatment options for gastrointestinal ascariasis include albendazole (400?mg PO once, for all ages), mebendazole (100?mg bid PO for 3 days or 500?mg PO once for all ages), or

pyrantel pamoate (11?mg/kg PO once; maximum: 1?g). Piperazine citrate (150?mg/kg PO initially, followed by six doses of 65?mg/kg at 12-hr intervals PO), which causes neuromuscular paralysis of the parasite and rapid expulsion of the worms, is the treatment of choice for intestinal or biliary obstruction and is administered as a syrup through a nasogastric tube. Surgery may be required for cases with severe obstruction.

Prevention.

Although ascariasis is the most prevalent worm infection in the world, little attention has been given to its control because of controversy surrounding its public health significance and the likelihood of recurrent infections in epidemiologic settings where transmission rates are high. Short-term preventive measures include chemotherapy. Anthelmintic chemotherapy programs can be implemented in one of three ways: (1) offering universal treatment to all individuals in an area of high endemicity; (2) offering treatment targeted to groups with high frequency of infection, such as children attending primary school; (3) offering individual treatment based on intensity of current or past infection. Improving sanitary conditions and sewage facilities, discontinuing the practice of using human feces as fertilizer, and education are the most effective long-term preventive measures.

Chapter 269 - Hookworms (*Ancylostoma* and *Necator americanus*)

Peter J. Hotez

Etiology.

Two major genera of hookworms, which are nematodes or roundworms, infect humans. Hookworms of the genus *Ancylostoma* include the major anthropophilic hookworm *Ancylostoma duodenale,* which causes classic hookworm infection, and the less common zoonotic species *A. ceylanicum, A. caninum,* and *A. braziliense.* Human zoonotic infection with the dog hookworm, *A. caninum,* has been linked to an eosinophilic enteritis syndrome. The larval stage of *A. braziliense,* whose definitive hosts include dogs and cats, is the principal cause of cutaneous larva migrans. *Necator americanus,* the only representative of its genus, is also a major anthropophilic hookworm and causes classic hookworm infection.

The infective larval stages of the anthropophilic hookworms live in a developmentally arrested state in warm, moist soil. The larvae infect humans either by penetrating through the skin (*N. americanus* and *A. duodenale*) or when they are ingested (*A. duodenale*). Larvae entering the human host by skin penetration undergo **extraintestinal migration** through the venous circulation and lungs before they are swallowed, whereas orally ingested larvae may either undergo extraintestinal migration or remain in the gastrointestinal tract. Larvae returning to the small intestine undergo two molts to become adult sexually mature male and female worms ranging in length from 5–13?mm. The buccal capsule of the adult hookworm is armed with teeth (*A. duodenale*) or cutting plates (*N. americanus*) to facilitate attachment to the mucosa and submucosa of the small intestine. Hookworms can remain in the intestine for 1–5 yr, where they mate and produce eggs. Although approximately 2 mo is required for the larval stages of hookworms to undergo extraintestinal migration and develop into mature adults, *A. duodenale* larvae may remain developmentally arrested for many months before resuming development in the intestine. Mature *A. duodenale* female worms produce about 30,000 eggs/24?hr; daily egg production by *N. americanus* is less than 10,000/24?hr. The eggs are thin-shelled and ovoid, measuring approximately 40 × 60?µ. Eggs that are deposited on soil with adequate moisture and shade develop into first-stage larvae and hatch. Over the ensuing several days, under appropriate conditions, the larvae molt twice to the infective stage. Infective larvae are developmentally arrested and nonfeeding. They migrate vertically in the soil until they either infect a new host or exhaust their

lipid metabolic reserves and die.

Epidemiology.

Hookworm infection is one of the most prevalent infectious diseases of humans, affecting an estimated 1 billion individuals worldwide. Because of the requirement for adequate soil moisture, shade, and warmth, hookworm infection is usually confined to rural areas, especially where human feces are used for fertilizer or where sanitation is inadequate. For that reason, hookworm is an infection associated with economic underdevelopment and poverty throughout the tropics and subtropics. High rates of infection are often associated with cultivation of certain agricultural products such as tea in India; sweet potato, corn, cotton, and mulberry trees in China; coffee in Central and South America; and rubber in Africa. China and India have the highest prevalence of hookworm infection. Wherever hookworm occurs, it is not uncommon to find patients with mixed *N. americanus* and *A. duodenale* infections. *N. americanus* predominates in Central and South America, as well as in South China and southeast Asia, whereas *A. duodenale* predominates in North Africa, in northern India, in China north of the Yangtze River, and among aboriginal people in western Australia. The ability of *A. duodenale* to withstand somewhat harsher environmental and climactic conditions may reflect its ability to undergo arrested development in human tissues. *A. ceylanicum* infection occurs in India and Southeast Asia.

Eosinophilic enteritis caused by *A. caninum* was first described in Queensland, Australia, with two reported cases in the United States. Because of its global distribution in dogs, it is anticipated that human *A. caninum* infections will be identified in many locales.

Pathogenesis.

The major morbidity of human hookworm infection is a direct result of intestinal blood loss. Adult hookworms adhere tenaciously to the mucosa and submucosa of the proximal small intestine by using their teeth (or cutting plates) and a muscular esophagus that creates negative pressure in their buccal capsules. At the attachment site, hookworms downregulate host inflammation by releasing anti-inflammatory polypeptides. Rupture of capillaries in the lamina propria is followed by blood extravasation; some of the blood is directly ingested by the hookworms, which anticoagulate blood through the release of peptides that block factor Xa and VIIa/tissue factor. Each adult *A. duodenale* hookworm causes loss of an estimated 0.2?mL of blood/24?hr; blood loss is less for *N. americanus.* Individuals with light infections suffer from very little blood loss and, consequently, may have *hookworm infection* but not *hookworm disease.* Hookworm disease results only when individuals with moderate and heavy infections experience sufficient blood loss to develop iron deficiency and anemia. Hypoalbuminemia and consequent edema and anasarca from the loss of intravascular oncotic pressure can also occur. These features depend heavily on the dietary reserves of the host.

Clinical Manifestations.

Heavily infected children suffer from intestinal blood loss resulting in iron deficiency, which can lead to anemia as well as protein malnutrition. Prolonged iron deficiency associated with hookworms in childhood can lead to physical growth retardation and cognitive and intellectual deficits.

Anthropophilic hookworm larvae elicit dermatitis sometimes referred to as **ground itch** when they penetrate human skin. The vesiculation and edema of ground itch are exacerbated by repeated infection. Infection with a zoonotic hookworm, especially *A. braziliense,* can result in lateral migration of the larvae to cause the characteristic cutaneous tracts of cutaneous larva migrans (see later text). Cough subsequently occurs in *A. duodenale* and *N. americanus* hookworm infection when larvae migrate through the lungs to cause laryngotracheobronchitis, usually about 1 wk after exposure. Pharyngitis also can occur.

Intestinal hookworm infection may occur without specific gastrointestinal complaints, although pain, anorexia, and diarrhea have been attributed to the presence of hookworms. Eosinophilia is often first noticed in the context of asymptomatic infection. The major clinical manifestations are related to intestinal blood loss. Heavily infected children exhibit all of the signs and symptoms of iron deficiency anemia and protein malnutrition. In some cases, children with chronic hookworm disease acquire a yellow-green pallor known as **chlorosis**.

An infantile form of ancylostomiasis resulting from heavy *A. duodenale* infection has been described. Affected infants experience diarrhea, melena, failure to thrive, and profound anemia. Infantile ancylostomiasis has significant mortality.

Eosinophilic enteritis caused by *A. caninum* is associated with colicky abdominal pain, usually exacerbated by food, which begins in the epigastrium and radiates outward. Extreme cases may mimic acute appendicitis.

Diagnosis.

Children with hookworm release eggs that can be detected by direct fecal examination (Fig. 269–1). Quantitative methods are available to determine whether a child has a heavy worm burden that can cause hookworm disease. The eggs of *A. duodenale* and *N. americanus* are morphologically indistinguishable. Species identification typically requires egg hatching and differentiation of third-stage infective larvae; newer methods using polymerase chain reaction methods are under development.

In contrast, eggs are generally not present in the feces of patients with eosinophilic enteritis caused by *A. caninum.* Eosinophilic enteritis is often diagnosed by demonstrating ileal and colonic ulcerations by colonoscopy in the presence of significant blood eosinophilia. An adult canine hookworm may occasionally be recovered during colonoscopic biopsy. Patients with this syndrome develop IgG and IgE serologic responses.

Treatment.

The goals of therapy are removal of the adult hookworms with an anthelmintic drug in addition to nutritional support for children with hookworm-associated iron deficiency and protein malnutrition. The benzimidazole anthelmintics, mebendazole and albendazole, are highly effective at eliminating hookworms from the intestine. Albendazole (400?mg PO once for all ages) achieves cure rates of up to 95%, although *N. americanus* adult hookworms are sometimes more refractory and require additional doses. Mebendazole (100?mg bid PO for 3 days or 500?mg PO once for all ages) is equally effective. Mebendazole is recommended for *A. caninum*-associated eosinophilic enteritis, although recurrences are common. Because the benzimidazoles have been reported to be embryotoxic and teratogenic in laboratory animals, their safety in young children is a potential concern. However, benzimidazole treatment of thousands of children in developing countries indicates that these agents are safe. Pyrantel pamoate (11?mg/kg PO once daily for 3 days; maximum dose: 1?g) is available in liquid form and is an effective alternative to the benzimidazoles. Replacement therapy with an iron salt preparation is often required to correct hookworm-associated iron deficiency.

Figure 269-1 Eggs of hookworm *Necator americanus* in early cleavage, as seen in freshly passed feces (×400).

Prevention.

Although anthelmintic drugs are effective at eliminating hookworms from the intestine, the high rates of reinfection among children suggest that drug chemotherapy alone is not effective for controlling hookworm in highly endemic areas. Improved sanitation, health education, avoidance of human feces as fertilizer, and economic development are still critical for reducing endemicity. Work is in progress to genetically engineer hookworm antigens to use as vaccines in humans.

269.1 Cutaneous Larva Migrans

Etiology.

Cutaneous larva migrans (creeping eruption) is caused by the larvae of several nematodes, primarily hookworms, which are not usually parasitic for humans. *A. braziliense,* a hookworm of dogs and cats, is the most common cause, but other animal hookworms (*A. caninum, Uncinaria stenocephala,* and *Bunostomum phlebotomum*) and human parasites (*N. americanus, A. duodenale,* and *Strongyloides stercoralis*) may also produce the disease.

Epidemiology.

Cutaneous larva migrans, which is usually caused by *A. braziliense,* is endemic to the southeastern United States and Puerto Rico.

Clinical Manifestations.

After penetrating the skin, larvae localize at the epidermal-dermal junction and migrate in this plane, moving at a rate of 1–2?cm/24?hr. The response to the parasite is characterized by raised, erythematous, serpiginous tracks, which occasionally form bullae (Fig. 269–2). These lesions may be single or numerous and are usually localized to an extremity, although any area of the body may be affected. As the organism migrates, new areas of involvement may appear every few days. Intense localized pruritus, without any systemic symptoms, may be associated with the lesions.

Diagnosis.

Cutaneous larva migrans is diagnosed by clinical examination of the skin. Patients are often able to recall the exact time and location of exposure because the larvae produce intense itching at the site of penetration. Eosinophilia may occur but is uncommon.

Treatment.

If left untreated, the larvae die, and the syndrome resolves within a few weeks to several months. Topical application of thiabendazole (10% of the oral suspension applied topically qid) or oral treatment with ivermectin (200?µg/kg daily PO for 1–2 days), or albendazole (400?mg daily PO for 3 days, for all

Figure 269.1-2 Creeping eruption of cutaneous larva migrans. (From Korting GW: *Hautkrankheiten bei Kindern und Jugendlichen.* Stuttgart, FK Schattauer Verlag, 1969.)

ages), hastens resolution and may be used if symptoms warrant treatment. Nausea and vomiting frequently preclude repeated administration of oral thiabendazole.

Chapter 270 - Trichuriasis (*Trichuris trichiura*)

Sheral S. Patel
James W. Kazura

Etiology.

Trichuriasis is caused by the **whipworm**, *Trichuris trichiura*, a nematode, or roundworm, that inhabits the cecum and ascending colon of humans. The principal hosts of *T. trichiura* are humans who acquire infection by ingesting embryonated, barrel-shaped eggs (Fig. 270–1). The larvae escape from the shell in the upper small intestine and penetrate the intestinal villi. The worms slowly move toward the cecum where the anterior three-fourths whiplike portion remains within the superficial mucosa and the short posterior end is free in the lumen. In 1–3 mo, egg deposition by the adult female worm begins producing 5,000–20,000 eggs/24?hr. After excretion in the feces, embryonic development occurs in 2–4 wk with optimal temperature and soil conditions.

Epidemiology.

Trichuriasis occurs throughout the world and is especially common in poor rural communities with inadequate sanitary facilities and soil contaminated with human or animal feces. Trichuriasis is one of the most prevalent human helminthiases, with an estimated one billion infected individuals worldwide. In many parts of the world where protein-energy malnutrition and anemia are common, the prevalence of *T. trichiura* infection can be as high as 95%. It is estimated that 2.2 million people are infected in the rural southeastern United States. The highest rate of infection occurs among children 5–15 yr of age. Infection develops after ingesting embryonated ova by direct contamination of hands, food (raw fruits and vegetables fertilized with human feces), or drink. Transmission can also occur indirectly through flies or other insects.

Clinical Manifestations.

Most persons harbor low worm burdens and do not have symptoms. Some individuals may have a history of right lower quadrant or vague periumbilical pain. Adult *Trichuris* suck approximately 0.005?mL of blood/worm/24?hr. Children, who are most likely to be heavily infected, frequently suffer from disease. Clinical manifestations include chronic dysentery, rectal prolapse, anemia, poor growth, as

well as developmental and cognitive deficits. There is no significant eosinophilia even though a portion of the worms is embedded in the mucosa of the large bowel.

Diagnosis.

Because egg output is so high, fecal smears frequently reveal the characteristic barrel-shaped ova of *T. trichiura*.

Treatment.

Mebendazole (100?mg bid PO for 3 days or 500?mg PO once for all ages) is a safe and effective drug, in part because it is poorly absorbed from the gastrointestinal tract. It reduces egg

Figure 270-1 Egg of *Trichuris trichiura*, as seen in freshly passed feces (× 1,000).

output by 90–99% and has cure rates of 70–90%. Albendazole (400?mg PO once for all ages) is an alternative but with heavy infections the daily dose of albendazole may have to be administered for 3 days.

Prevention.

Disease can be prevented by personal hygiene, improved sanitary conditions, and eliminating the use of human feces as fertilizer.

Chapter 271 - Enterobiasis (*Enterobius vermicularis*)

Sheral S. Patel
James W. Kazura

Etiology.

The cause of enterobiasis, or **pinworm** infection, is *Enterobius vermicularis*, which is a small (1?cm in length), white, threadlike nematode, or roundworm, that typically inhabits the cecum, appendix, and adjacent areas of the ileum and ascending colon. Gravid females migrate at night to the perianal and perineal regions where they deposit eggs. Ova are convex on one side and flattened on the other and have diameters of ~30 × 60 *µ*m. Eggs embryonate within 6?hr and remain viable for 20 days. Human infection occurs by ingestion of embryonated eggs that are carried on fingernails, clothing, bedding, or house dust. After ingestion, the larvae mature to form adult worms in 36–53 days.

Epidemiology.

Enterobiasis infection occurs in individuals of all ages and socioeconomic levels. It is prevalent in regions with temperate climates and is the most common helminth infection in the United States. Infection occurs primarily in institutional or family settings that include children. The prevalence of pinworm infection is highest in children from 5–14 yr of age. It is common in areas where children live, play, and sleep close together, thus facilitating egg transmission. Because the life span of the adult worm is short, chronic parasitism is likely due to repeated cycles of reinfection. Autoinoculation can occur in individuals who habitually put their fingers in their mouth.

Pathogenesis.

Enterobius infection may cause symptoms by mechanical stimulation and irritation, allergic reactions, and migration of the worms to anatomic sites where they become pathogenic.

Clinical Manifestations.

Pinworm infection is innocuous and rarely causes serious medical problems. The

most common complaints include itching and restless sleep secondary to nocturnal perianal or perineal pruritus. The precise cause and incidence of pruritus are unknown. They may be related to the intensity of infection, psychological profile of the infected individual and his or her family, or allergic reactions to the parasite. Eosinophilia is not observed in most cases because tissue invasion does not occur. Perianal granulomas containing live or dead worms or eggs develop rarely but may require surgical excision. Aberrant migration to ectopic sites occasionally may lead to appendicitis, chronic salpingitis, peritonitis, hepatitis, and ulcerative lesions in the large or small bowel.

Diagnosis.

A history of nocturnal perianal pruritus in children strongly suggests enterobiasis. Definitive diagnosis is established by identification of parasite eggs or worms. Microscopic examination of adhesive cellophane tape pressed against the perianal region early in the morning frequently demonstrates eggs (Fig. 271–1). Repeated examinations increase the chance of detecting ova; a single examination detects 50% of infections, three examinations 90%, and five examinations 99%. Worms seen in the perianal region should be removed and preserved in 75% ethyl alcohol until microscopic examination can be performed. Digital rectal examination may also be used to obtain samples for a wet mount. Routine stool samples rarely demonstrate *Enterobius* ova.

Treatment.

Anthelmintic drugs should be administered to infected individuals and their family members. A single oral dose of mebendazole (100?mg PO for all ages) repeated in 2 wk results in cure rates of 90–100%. Alternative regimens include a single oral dose of albendazole (400?mg PO for all ages) repeated in 2 wk or a single dose of pyrantel pamoate (11?mg/kg PO, maximum: 1?g).

Prevention.

Repeated treatments every 3–4 mo may be required in circumstances with repeated exposure, such as with institutionalized children. Although personal cleanliness is a useful general principle, there is no evidence that it has a role in the control or prevention of enterobiasis.

Chapter 272 - Strongyloidiasis (*Strongyloides stercoralis*)

Sheral S. Patel
James W. Kazura

Etiology.

Strongyloidiasis is caused by the nematode, or roundworm, *Strongyloides stercoralis*. Only adult female worms inhabit the small intestine. The nematode reproduces in the human host by parthenogenesis and releases eggs containing mature larvae into the intestinal lumen. Rhabditiform larvae immediately emerge from the ova and are passed in feces, where they can be visualized by stool examination. Rhabditiform larvae either differentiate into free-living adult male and female worms or metamorphose into the infectious filariform larvae. Humans are usually infected through skin contact with soil contaminated with infectious larvae. Larvae penetrate the skin, enter the venous circulation and then pass to the lungs, break into alveolar spaces, and migrate up the bronchial tree. They are then swallowed and pass through the stomach, and adult female worms develop in the small intestine. Egg deposition begins about 28 days after initial infection.

The **hyperinfection syndrome** occurs when large numbers of larvae transform into infective organisms during their passage in feces and then reinfect (i.e., autoinfect) the host by way of the lower gastrointestinal tract or perianal region. This cycle may be accelerated in immunocompromised persons, particularly those with depressed T-cell function.

Epidemiology.

S. stercoralis infection is prevalent in tropical and subtropical regions of the world and endemic in several areas of Europe, the southeastern United States, and Puerto Rico. Transmission requires appropriate environmental conditions, particularly warm, moist soil. Poor sanitation and crowded living conditions are conducive to high levels of transmission. The highest prevalence of infection in the United States (4% of the general population) is in impoverished rural areas of Kentucky and Tennessee. Infection may be especially common among residents of mental institutions, veterans who were prisoners of war in areas of high endemicity, and refugees and immigrants. Individuals with hematologic malignancies, autoimmune diseases, malnutrition, and drug-induced immunosuppression are at high risk of the hyperinfection syndrome. Patients with AIDS may experience a rapid course of disseminated strongyloidiasis with a fatal outcome.

Pathogenesis.

The initial host immune response to infection is production of IgE and eosinophilia in blood and tissues, which presumably prevents dissemination and hyperinfection in the immunocompetent host. Adult female worms in otherwise healthy and asymptomatic individuals may persist in the gastrointestinal tract for years. If infected persons become immunocompromised, the reduction in cellular and humoral immunity may lead to an abrupt and dramatic increase in parasite load with systemic dissemination.

Clinical Manifestations.

Approximately one third of infected individuals are asymptomatic. The remaining two thirds have symptoms that correlate with the three stages of infection: invasion of the skin, migration of larvae through the lungs, and parasitism of the small intestine by adult worms. **Larva currens** is the manifestation of an allergic reaction to filariform larvae that migrate through the skin, where they leave pruritic, tortuous, urticarial tracks. The lesions may recur and are typically found over the lower abdominal wall, buttocks, or thighs. Pulmonary disease secondary to larval migration through the lung rarely occurs and may resemble Löffler's syndrome (cough, wheezing, shortness of breath, and transient pulmonary infiltrates accompanied by eosinophilia). Gastrointestinal strongyloidiasis is characterized by indigestion, crampy abdominal pain, vomiting, diarrhea, steatorrhea, protein-losing enteropathy, and weight loss. Edema of the duodenum with irregular mucosal folds, ulcerations, and strictures can be seen radiographically.

Strongyloidiasis is potentially lethal because of the ability of the parasite to cause overwhelming hyperinfection in immunocompromised persons. The **hyperinfection syndrome** is characterized by an exaggeration of the clinical features that develop in symptomatic immunocompetent individuals. The onset is usually sudden with generalized abdominal pain, distention, and fever. Multiple organs can be affected as massive numbers of larvae disseminate throughout the body and introduce bowel flora. The latter may result in bacteremia and septicemia. Cutaneous manifestations may include petechiae and purpura. Cough, wheezing, and hemoptysis are indicative of pulmonary involvement. Whereas eosinophilia is a prominent feature of strongyloidiasis in immunocompetent persons, this sign may be absent in immunocompromised persons.

Diagnosis.

Intestinal strongyloidiasis is diagnosed by examining feces or duodenal fluid for the characteristic larvae (Fig. 272–1). Several stool samples should be examined either by direct smear or a concentration method such as formaldehyde-ether or the Baermann test. Alternatively, duodenal fluid can be sampled by the **enteric string test** (Entero-Test) or aspiration. In children with the hyperinfection syndrome, larvae may be found in sputum, gastric aspirates, and rarely in small intestinal biopsy specimens. An enzyme-linked immunosorbent assay for IgE antibody to

Strongyloides may be more sensitive than parasitologic methods for diagnosing intestinal infection in the immunocompetent host. The utility of the assay in diagnosing infection in immunocompromised subjects with the hyperinfection syndrome has not been determined.

Treatment.

Treatment is directed at eradication of infection. A recent study showed that ivermectin (200?µg/kg/24?hr once daily PO for 1–2 days), which is the drug of choice for uncomplicated strongyloidiasis, is equally effective and associated with fewer adverse effects than thiabendazole (50?mg/kg bid PO for 2 days; maximum: 3?g/24?hr), which is the traditional treatment. Patients with the hyperinfection syndrome should be treated with ivermectin for 7–10 days and may require repeated courses. Reducing the dose of immunosuppressive therapy and treatment of concomitant bacterial infections are essential in the management of the hyperinfection syndrome. Close follow-up with repeated stool examination is necessary to ensure complete elimination of the parasite.

Prevention.

Sanitary practices designed to prevent soil and person-to-person transmission are the most effective control measures. Wearing shoes is a main preventive strategy. Reduction in transmission in institutional settings can be achieved by decreasing fecal contamination of the environment such as by the use of clean bedding. Because infection is uncommon in most settings, case detection and treatment are advisable. Individuals who will be given immunosuppressive drugs before organ transplantation or cancer chemotherapy should have a

Figure 272-1 Larvae of intestinal strongyloidiasis.

screening examination for *S. stercoralis*. If infected, they should be treated before immunosuppression is induced. **REFERENCES**

Chapter 273 - Lymphatic Filariasis (*Brugia malayi, Brugia timori, Wuchereria bancrofti*)

Sheral S. Patel
James W. Kazura

Etiology.

The filarial worms *Brugia malayi* (**Malayan filariasis**), *Brugia timori,* and *Wuchereria bancrofti* (**bancroftian filariasis**) are threadlike nematodes that cause similar infections. Infective larvae are introduced into humans during blood feeding by the mosquito vector. Over a period of 4–6 mo, the larval forms develop into adult worms that reside in the afferent lymphatic vessels. Sexually mature adult female worms release large numbers of microfilariae that circulate in the bloodstream. The life cycle of the parasite is completed when mosquitoes ingest microfilariae in a blood meal and molt to form infective larvae over a period of 10–14 days.

Epidemiology.

More than 120 million people living in tropical Africa, Asia, and Latin America are infected; approximately 10–20% of these individuals have clinically significant morbidity attributable to filariasis. *W. bancrofti* is transmitted in Africa, Asia, and Latin America. *B. malayi* is restricted to the South Pacific and Southeast Asia, and *B. timori* is restricted to several islands of Indonesia. Travelers from nonendemic areas of the world who spend brief periods of time in endemic areas are rarely infected.

Clinical Manifestations.

The clinical manifestations of *B. malayi, B. timori,* and *W. bancrofti* infection are similar; manifestations of acute infection include transient, recurrent lymphadenitis and lymphangitis, whereas chronic filariasis is characterized by lymphatic obstruction with hydrocele and elephantiasis. The early signs and symptoms include episodic fever, lymphangitis of an extremity, lymphadenitis (especially the inguinal and axillary areas), headaches, and myalgia that last a few days to several weeks. The syndrome is most frequently observed in young persons 10–20 yr of age. Manifestations of chronic lymphatic filariasis, such as hydrocele and elephantiasis, occur mostly in adults 30 yr of age or older and result from anatomic and functional obstruction to lymph flow. Elephantiasis may involve one or more limbs, the scrotum, the breasts, or the vulva. It is uncommon for children to have overt signs of chronic filariasis.

TROPICAL PULMONARY EOSINOPHILIA.

The presence of microfilariae in the body has no apparent pathologic consequences except in persons with tropical pulmonary eosinophilia, a syndrome of filarial etiology in which microfilariae are found in the lungs and lymph nodes but not bloodstream. It occurs only in individuals who have lived for years in endemic areas. Men 20–30 yr of age are most likely to be affected, although the syndrome occasionally occurs in children. The presentation includes paroxysmal nocturnal cough with dyspnea, fever, weight loss, and fatigue. Rales and rhonchi are found on auscultation of the chest. The roentgenographic findings may occasionally be normal but increased bronchovascular markings, discrete opacities in the middle and basal regions of the lung, or diffuse miliary lesions are usually present. Recurrent episodes may result in interstitial fibrosis and chronic respiratory insufficiency in untreated individuals. Hepatosplenomegaly and generalized lymphadenopathy are often seen in children. The diagnosis is suggested by residence in a filarial endemic area, eosinophilia (>2,000/µL), compatible clinical symptoms, increased serum IgE (>1,000?IU/mL), and high titers of antimicrofilarial antibodies in the absence of microfilaremia. Although microfilariae may be found in sections of lung or lymph node, biopsy of these tissues is unwarranted in most situations. The clinical response to diethylcarbamazine (5?mg/kg/24?hr PO for 10 days) is the final criterion for diagnosis; the majority of patients improve with this therapy. If symptoms recur, a second course of the anthelmintic should be administered. Patients with chronic symptoms are less likely to show improvement than those who have been ill for a short time.

Diagnosis.

Demonstration of microfilariae in the blood is the primary means for confirming the diagnosis of lymphatic filariasis. Because microfilaremia is nocturnal in most cases, blood samples should be obtained between 10 o'clock at night and 2 o'clock in the morning. Anticoagulated blood is passed through a Nuclepore filter that is stained and examined microscopically for microfilariae. Infection with *W. bancrofti* in the absence of blood-borne microfilariae may be diagnosed by detection of parasite antigen in the serum.

Treatment.

The use of antifilarial drugs in the management of acute lymphadenitis and lymphangitis is controversial. No controlled studies demonstrate that administration of drugs such as diethylcarbamazine modifies the course of acute lymphangitis. Diethylcarbamazine may be given to asymptomatic microfilaremic persons to lower the intensity of parasitemia. The drug also kills a proportion of the adult worms. Because treatment-associated complications such as pruritus, fever, generalized body pain, hypertension, and even death may occur, especially with high microfilarial levels, the dose of diethylcarbamazine should be increased gradually (children:

1?mg/kg PO as a single dose on day 1; 1?mg/kg tid PO on day 2; 1–2?mg/kg tid PO on day 3; and 6?mg/kg/24?hr divided tid PO on days 4–14; adults: 50?mg PO on day 1; 50?mg tid PO on day 2; 100?mg tid PO on day 3; and 6?mg/kg/24?hr divided tid PO on days 4–14). For patients with no microfilaria in the blood, the full dose (6?mg/kg/24?hr divided tid PO) can be given beginning on day 1. Repeat doses may be necessary to reduce further the microfilaremia and kill lymph-dwelling adult parasites. *W. bancrofti* is more sensitive than *B. malayi* to diethylcarbamazine.

Chapter 274 - Other Tissue Nematodes

Sheral S. Patel
James W. Kazura

ONCHOCERCIASIS (*ONCHOCERCA VOLVULUS*)

Infection with *Onchocerca volvulus* leads to onchocerciasis or river blindness. Onchocerciasis occurs primarily in West Africa but also Central and East Africa. There are scattered foci in Central and South America. *O. volvulus* larvae are transmitted to humans by way of the bite of *Simulium* blackflies that breed in fast-flowing streams. The larvae penetrate the skin and migrate through the connective tissue and eventually develop into adult worms that can be found tangled in fibrous tissue. Female worms produce large numbers of microfilariae that migrate through the skin and connective tissue. Most infected individuals are asymptomatic. In heavily infected subjects, clinical manifestations are due to localized host inflammatory reactions to dead or dying microfilariae. These reactions produce pruritic dermatitis, punctate keratitis, corneal pannus formation, and chorioretinitis. Adult worms in subcutaneous nodules are not painful and tend to occur over bony prominences of the hip. The diagnosis can be established by obtaining snips of skin covering the scapulae, iliac crests, buttocks, or calves. The snips are immersed in saline for several hours and examined microscopically for microfilariae that have emerged into the fluid. The diagnosis can also be established by demonstrating microfilariae in the cornea or anterior chamber on slit-lamp examination or finding adult worms on a nodule biopsy specimen. Ophthalmology consultation should be obtained before treatment of eye lesions. A single dose of ivermectin (150?µg/kg PO) is the drug of choice and clears microfilariae from the skin for several months, but it has no effect on the adult worm. Treatment with ivermectin should be repeated at 3–6 mo intervals if there are continuing symptoms or evidence of eye infection. Adverse effects of ivermectin therapy include fever, urticaria, and pruritus and are more frequent in individuals not born in endemic areas who acquired the infection following periods of intense exposure, such as Peace Corps volunteers. Patients with concurrent loiasis may develop encephalopathy with ivermectin therapy. Personal protection includes avoiding areas where biting flies are numerous, wearing protective clothing, and using insect repellant. Vector control and mass ivermectin distribution programs have been implemented in Africa in an effort to eradicate onchocerciasis.

LOIASIS (*LOA LOA*)

Loiasis is caused by infection with the tissue nematode *Loa loa*. The parasite is transmitted to humans via diurnally biting flies (*Chrysops*) that live in the rain forests of West and Central Africa. Migration of adult worms through skin, subcutaneous tissue, and subconjunctivae can lead to transient episodes of pruritus, erythema, localized edema known as **Calabar swellings**, which are nonerythematous areas of subcutaneous edema 10–20?cm in diameter that are typically found around joints such as the wrist or the knee (Fig. 274–1), or eye pain. They resolve over several days to weeks and may recur at the same or different sites. Although lifelong residents of endemic regions may have microfilaremia and eosinophilia, these individuals are often asymptomatic. In contrast, travelers to endemic regions may have a hyperreactive response to *L. loa* infection characterized by frequent recurrences of swelling, high level eosinophilia, debilitation, and serious complications such as glomerulonephritis and encephalitis. Diagnosis is usually established on clinical grounds. Microfilariae may be detected in blood smears collected between 10 o'clock in the morning and 2 o'clock in the afternoon. Adult worms should be surgically excised when possible. Diethylcarbamazine is the agent of choice for eradication of microfilaremia but the drug does not kill adult worms. Because treatment-associated complications such as pruritus, fever, generalized body pain, hypertension,

Figure 274-1 Calabar swelling of the right hand. (From Guerrant et al: *Tropical Infectious Diseases*. Churchill Livingstone, 1999, p. 863.)

and even death may occur, especially with high microfilarial levels, the dose of diethylcarbamazine should be increased gradually (children: 1?mg/kg PO on day 1; 1?mg/kg tid PO on day 2; 1–2?mg/kg tid PO on day 3; 9?mg/kg/24?hr divided tid PO on days 4–21; adults: 50?mg PO on day 1; 50?mg tid PO on day 2; 100?mg tid PO on day 3; 9?mg/kg/24?hr divided tid PO on days 4–21). Full doses can be instituted on day 1 in persons without microfilaremia. Individuals concurrently infected with *O. volvulus* are at increased risk of developing encephalopathy with ivermectin treatment. A single dose of ivermectin (200?µg/kg) decreases microfilarial densities in the blood in persons with high-density microfilaremia. A 3-wk course of albendazole can also be used to slowly reduce microfilarial levels as a result of embryotoxic effects on the adult worms. Antihistamines or corticosteroids may be used to limit allergic reactions secondary to killing of microfilariae. Personal protective measures include avoiding areas where biting flies are present, wearing protective clothing, and using insect repellants. Diethylcarbamazine (300?mg PO once weekly) prevents infection in travelers who spend prolonged periods of time in endemic areas.

INFECTION WITH ANIMAL FILARIAE

The most commonly recognized zoonotic filarial infections are caused by members of the genus *Dirofilaria.* The worms are introduced into humans by the bites of mosquitoes containing third-stage larvae. The most common filarial zoonosis in the Unites States is *Dirofilaria tenuis*, a parasite of raccoons. In Europe, Africa, and Southeast Asia, infections are most commonly caused by the dog parasite *Dirofilaria repens.* The **dog heartworm**, *Dirofilaria immitis*, is the second most commonly encountered filarial zoonosis worldwide. Other genera including *Dipetalonema*-like worms, *Onchocerca,* and *Brugia* are rare causes of zoonotic filarial infections.

Animal filariae do not undergo normal development in the human host. The clinical manifestations and pathologic findings correspond to the anatomic site of infection and can be categorized into four major groups: subcutaneous, lung, eye, and lymphatic. Pathologic examination of affected tissue reveals a localized foreign body reaction around a dead or dying parasite. The lesion consists of granulomas with eosinophils, neutrophils, and tissue necrosis. *D. tenuis* does not leave the subcutaneous tissues, whereas *B. beaveri* eventually localizes to superficial lymph nodes. Infections may be present for up to several months. *D. immitis* larvae migrate for several months in subcutaneous tissues and most frequently result in a well-circumscribed coinlike lesion in a single lobe of the lung. The chest radiograph typically reveals a solitary pulmonary nodule 1–3?cm in diameter. Definitive diagnosis and cure depend on surgical excision and identification of the nematode within the surrounding granulomatous response. *D. tenuis* and *B. beaveri* infections present as painful 1–5?cm rubbery nodules in the skin of the trunk, extremities, and around the orbit. Patients often report having been engaged in activities predisposing to exposure to infected mosquitoes, such as working or hunting in swampy areas. Diagnosis and management is by surgical excision.

ANGIOSTRONGYLUS CANTONENSIS

Angiostrongylus cantonensis, the **rat lungworm**, is the most common cause of eosinophilic meningitis worldwide. Rats are the definitive host. Human infection follows ingestion of third-stage larvae in raw or undercooked intermediate hosts such as snails and slugs, or transport hosts such as freshwater prawns, frogs, and fish. Most cases are sporadic but clusters have been reported, including consumption of lettuce contaminated with intermediate or transport hosts. Even though most infections have been described in Southeast Asia, the South Pacific, and Taiwan, shipboard travel of infected rats has spread the parasite to Madagascar, Africa, Caribbean, and, most recently, Australia and North America. Larvae penetrate the vasculature of the intestinal tract and migrate to the meninges, where they usually die but induce eosinophilic aseptic meningitis. Patients present 2–35 days after ingestion of larvae with severe headache, neck pain or nuchal rigidity, hyperesthesias and paresthesias, fatigue, fever, rash, pruritus, nausea, and vomiting. Neurologic involvement varies from asymptomatic to paresthesias, severe pain, weakness, and focal neurologic findings such as cranial nerve palsies. Coma and death due to hydrocephalus occur rarely in heavy infections. Peripheral blood eosinophilia is not always present on initial examination, but peaks about 5 wk after exposure, often when symptoms are improving. Cerebrospinal (CSF) fluid analysis reveals pleocytosis with >10% eosinophils in more than half of patients, with mildly elevated protein and normal glucose levels. The diagnosis is established clinically with supporting travel and diet history. A sensitive and specific enzyme-linked immunosorbent assay (ELISA) is available on a limited basis from the Centers for Disease Control and Prevention for testing either CSF or serum. Treatment is primarily supportive because the majority of infections are mild and most patients recover within 2 mo without neurologic residua. Analgesics should be given for

headache. Careful, repeated lumbar punctures should be performed to relieve hydrocephalus. Anthelmintic drugs have not been shown to influence the outcome and may exacerbate neurologic symptoms. The use of corticosteroids may shorten the duration of symptoms for persistent and severe headaches. There is a higher incidence of permanent neurologic sequelae and mortality among children than among adults. Infection can be avoided by not eating raw or undercooked crabs, prawns, or snails.

ANGIOSTRONGYLUS COSTARICENSIS

Angiostrongylus costaricensis is a nematode that infects several species of rodents and causes abdominal angiostrongyliasis, which has been described predominantly in Latin America and the Caribbean. The mode of transmission to humans, who are accidental hosts, is unknown. It is speculated that infectious larvae from a molluscan intermediate host, such as the slug *Vaginulus plebeius*, contaminate water or vegetation that are inadvertently consumed (e.g., chopped up in salads or on vegetation contaminated with their mucus secretions). Although this slug is not indigenous to the continental United States, it has been found on imported flowers and produce. A study of 116 Costa Rican children with clinical abdominal angiostrongyliasis reported that the disease was twice as frequent in males as females and occurred predominantly during the rainy season in children 6–13 yr of age and of relatively high socioeconomic status. The incubation period for abdominal angiostrongyliasis is unknown but limited data suggest it ranges from 2 wk to several months after ingestion of larvae. Third-stage larvae migrate from the gastrointestinal tract to the mesenteric arteries where they mature into adults. These eggs degenerate and elicit an eosinophilic granulomatous reaction. The clinical findings of abdominal angiostrongyliasis mimic appendicitis although the former are typically more indolent. Children can have fever, right lower quadrant pain, a tumor-like mass, abdominal rigidity, and painful rectal examination. Most patients have leukocytosis with eosinophilia. Radiologic examination may show bowel wall edema, spasticity, or filling defects in the ileocecal region and the ascending colon. Examination of stool for ova and parasites is not useful for *A. costaricensis* but is useful for evaluating the presence of other intestinal parasites. An ELISA is available for diagnosis on a limited basis from the Centers for Disease Control and Prevention but the specificity of the test is low and it is known to cross-react with *Toxocara, Strongyloides,* and *Paragonimus.* Many patients undergo laparotomy for suspected appendicitis and are found to have a mass in the terminal

ileum to the ascending colon. No specific treatment is known for abdominal angiostrongyliasis. Even though the use of anthelmintic therapy has not been studied systematically, thiabendazole or diethylcarbamazine has been suggested. The prognosis is generally good. Most cases are self-limited, although surgery may be required in some patients. Cornerstones of prevention include avoidance of slugs and not ingesting raw food and water that may be contaminated with imperceptible slugs or slime from slugs. Rat control is also important in preventing the spread of infection.

DRACUNCULIASIS (*DRACUNCULUS MEDINENSIS*)

Dracunculiasis is caused by the guinea worm, *Dracunculus medinensis*. The infection is confined to 13 countries in Africa with approximately 61% of the 79,000 annual reported cases occurring in Sudan. Humans become infected by drinking contaminated stagnant water containing immature forms of the parasite in the gut of tiny crustaceans (copepods). Larvae are released in the stomach, penetrate the mucosa, mature, and mate. About 1 yr later, the adult female worm (1–2?mm in diameter and up to 1?m long) migrates and partially emerges through the skin, usually of the legs. Thousands of immature larvae are released when the affected body part is immersed in the water. The cycle is completed when larval forms are ingested by the crustaceans. Infected humans have no symptoms until the worm reaches the subcutaneous tissue, causing a stinging papule that may be accompanied by urticaria, nausea, vomiting, diarrhea, and dyspnea. The lesion vesiculates, ruptures, and forms a painful ulcer in which a portion of the worm is visible. Diagnosis is established clinically. Larvae can be identified by microscopic examination of the discharge fluid. Metronidazole (25?mg/kg tid PO for 10 days: maximum dose: 750?mg) decreases local inflammation. Although the drug does not kill the worm, it facilitates its removal by a process rolling the emerging 1-m long parasite onto a thin stick over a week. Topical corticosteroids shorten the time to complete healing while topical antibiotics decrease the risk of secondary bacterial infection. Dracunculiasis can be prevented by boiling or chlorinating drinking water or passing the water through a cloth sieve before consumption.

GNATHOSTOMA SPINIGERUM

Gnathostoma spinigerum is a dog and cat nematode endemic to Southeast Asia, Japan, China, Bangladesh, and India. Infection is acquired by ingesting intermediate hosts containing larvae of the parasite such as raw or undercooked freshwater fish, chickens, pigs, snails, or frogs. Penetration of the skin by larval forms and prenatal transmission has also been described. Nonspecific signs and symptoms such as generalized malaise, fever, urticaria, anorexia, nausea, vomiting, diarrhea, and epigastric pain develop 24–48?hr after ingestion of *G. spinigerum*. Moderate to severe eosinophilia develops as larvae penetrate the gastric or intestinal wall and migrate through various tissues. Cutaneous gnathostomiasis is manifest as intermittent episodes of localized, migratory nonpitting edema associated with pain, pruritus, or erythema. Central nervous system involvement in gnathostomiasis is suggested by focal neurologic findings, initially neuralgia followed within a few days by paralysis or changes in mental status. Multiple cranial nerves may be involved, and the cerebrospinal fluid typically shows an eosinophilic pleocytosis. Diagnosis of gnathostomiasis is based on clinical presentation and epidemiologic background. Serologic testing varies in sensitivity and specificity and is not widely available. There is no well-documented effective chemotherapy, although albendazole (400?mg PO bid for 21 days) has been suggested to be useful. Surgical resection of the *Gnathostoma* is the major mode of therapy and the treatment of choice. Blind surgical resection of subcutaneous areas of diffuse swelling is not recommended because the worm can rarely be located. Prevention through the avoidance of ingestion of poorly cooked or raw fish, poultry, or pork should be emphasized for individuals living in or visiting endemic areas.

Chapter 275 - Toxocariasis (Visceral and Ocular Larva Migrans)

Sheral S. Patel
James W. Kazura

Etiology.

Most cases of human toxocariasis are caused by the **dog roundworm**, *Toxocara canis*. Adult female *T. canis* worms live in the intestinal tracts of young puppies and their lactating mothers. Large numbers of eggs are passed in the feces of dogs and embryonate under optimal soil conditions. *Toxocara* eggs can survive relatively harsh environmental conditions and are resistant to freezing and extremes of moisture and pH. Humans ingest embryonated eggs contaminating soil, hands, or fomites. The larvae hatch and penetrate the intestinal wall and travel by way of the circulation to the liver, lung, and other tissues. Humans do not excrete *T. canis* eggs because the larvae are unable to complete their maturation to adult worms in the intestine. The **cat roundworm**, *T. cati*, is responsible for far fewer cases of visceral larva migrans than *T. canis*. Ingestion of

infective larvae of the raccoon and opossum ascarids *Baylisascaris procyonis* and *Lagochilascaris minor* can rarely lead to visceral larva migrans.

Epidemiology.

Human *T. canis* infections have been reported in nearly all parts of the world, primarily in temperate and tropical areas where dogs are popular household pets. Young children are at highest risk because of their unsanitary play habits and tendency to place fingers in the mouth. Other behavioral risk factors include pica, contact with puppy litters, and institutionalization. In North America, the highest prevalences of infection are in the southeastern United States and Puerto Rico, particularly among socially disadvantaged African-American and Hispanic children. The highest reported frequency of infection in the world is in a village in Saint Lucia where 86% of children between the ages 6 mo and 6 yr were found to be seropositive. The high rate of infection in this community was attributed to a high prevalence of canine toxocariasis, widespread contamination of peridomestic areas with infective eggs, and pica. Assuming an unrestrained and untreated dog population, toxocariasis is prevalent in settings where other geohelminth infections such as ascariasis, trichuriasis, and hookworm infections are common.

Pathogenesis.

T. canis larvae secrete large amounts of immunogenic glycosylated proteins. These antigens induce immune responses that lead to eosinophilia and polyclonal and antigen-specific IgE production. The characteristic histopathologic lesions are granulomas containing eosinophils, multinucleated giant cells (histiocytes), and collagen. Granulomas are typically found in the liver but may also occur in the lungs, central nervous system, and ocular tissues. Clinical manifestations reflect the intensity and chronicity of infection, anatomic localization of larvae, and host granulomatous responses.

Clinical Manifestations.

There are three major clinical syndromes associated with human toxocariasis: visceral larva migrans (VLM), ocular larva migrans (OLM), and covert toxocariasis (Table 275–1). The classic presentation of VLM includes eosinophilia, fever, and hepatomegaly, and occurs most commonly in toddlers with a history of pica and exposure to puppies. The findings include fever, cough, wheezing, bronchopneumonia, anemia, hepatomegaly, leukocytosis, eosinophilia, and positive *Toxocara* serology. OLM tends to occur in older children without signs or symptoms of VLM. Presenting symptoms include unilateral visual loss, eye pain, white pupil, or strabismus that develops over a period of weeks. Granulomas occur on the posterior pole of the retina and may be mistaken for retinoblastoma. Serologic testing for *Toxocara* has allowed the identification of individuals with less obvious or covert symptoms of infection. These children may have nonspecific complaints that do not constitute a recognizable syndrome. Common findings include hepatomegaly, abdominal pain, cough, sleep disturbance, failure to thrive, and

TABLE 275-1 -- **Clinical Syndromes of Human Toxocariasis**

Syndrome	Clinical Findings	Average Age	Infectious Dose	Incubation Period	Laboratory Findings	ELISA
Visceral larva migrans	Fevers, hepatomegaly, asthma	5 yr	Moderate to high	Weeks to months	Eosinophilia, leukocytosis, elevated IgE	High (=1:16)
Ocular larva migrans	Visual disturbances, retinal granulomas, endophthalmitis, peripheral granulomas	12 yr	Low	Months to years	Usually none	Low (<1:512)

Covert toxocariasis	Abdominal pain, gastrointestinal symptoms, weakness, hepatomegaly, pruritus, rash	School age to adult	Low to moderate	Weeks to years	± Eosinophilia, ± elevated IgE	Low to moderate

ELISA, enzyme-linked immunosorbent assay; ±, with or without.

Adapted from Liu LX: Toxocariasis and larva migrans syndrome. In Guerrant RL, Walker DH, Weller PF (editors): Tropical Infectious Diseases: Principles, Pathogens & Practice. Philadelphia, Churchill-Livingstone, 1999, p. 908.

headache with elevated *Toxocara* antibody titers. Eosinophilia may be present in only 50–75% of cases. The prevalence of positive *Toxocara* serology in the general population supports the notion that most children with *T. canis* infection are asymptomatic and will not develop overt clinical sequelae over time. A correlation between positive *Toxocara* serology and allergic asthma has also been described.

Diagnosis.

A presumptive diagnosis can be established in a young child with eosinophilia, leukocytosis, hepatomegaly, fevers, wheezing, and a history of geophagia and exposure to puppies or unrestrained dogs. Supportive laboratory findings include hypergammaglobulinemia and elevated isohemagglutinin titers to A and B blood group antigens. Most patients with VLM have an absolute eosinophil count of 500/µL or greater. Eosinophilia is less common in subjects with OLM. An enzyme-linked immunosorbent assay using excretory-secretory proteins harvested from *T. canis* larvae maintained in vitro is the standard serologic test used to confirm toxocariasis. The sensitivity is >75% and specificity >90% using a cutoff dilution of 1:32. The diagnosis of OLM can be established in patients with typical clinical findings of a retinal or peripheral pole granuloma or endophthalmitis with elevated antibody titers. Vitreous and aqueous humor fluid anti-*Toxocara* titers are usually greater than serum titers. The diagnosis of covert toxocariasis should be considered in individuals with chronic weakness, abdominal pain, or allergic signs with eosinophilia and increased IgE. In temperate regions of the world, nonparasitic causes of eosinophilia that should be considered in the differential diagnosis include allergies, drug hypersensitivity, lymphoma, vasculitis, and the idiopathic hypereosinophilic syndrome (see Chapter 119).

Treatment.

Most cases do not require treatment because signs and symptoms are mild and subside over a period of weeks to months. Several anthelmintic drugs have been used for symptomatic cases, often with adjunctive corticosteroids to limit inflammatory responses that presumably result from release of *Toxocara* antigens by dying parasites. Albendazole (400?mg once daily PO for 5 days for all ages) has demonstrated efficacy in both children and adults. Mebendazole (100–200?mg bid PO for 5 days for all ages) is also useful. Even though there are no clinical trials regarding therapy of OLM, a course of oral corticosteroids such as prednisone (1?mg/kg/24?hr PO for 2–4 wk) has been recommended to suppress local inflammation while treatment with anthelmintic agents is initiated.

Prevention.

Transmission can be minimized by public health measures that prevent dog feces from contaminating the environment. These include keeping dogs on leashes and excluding pets from playgrounds and sandboxes that toddlers use. Children should be discouraged from putting dirty fingers in their mouth and eating dirt. Vinyl covering of sandboxes reduces the viability

of *T. canis* eggs. Widespread veterinary use of broad-spectrum anthelmintics effective against *Toxocara* may lead to a decline in parasite transmission to humans.

Chapter 276 - Trichinosis (*Trichinella spiralis*)

Sheral S. Patel
James W. Kazura

Etiology.

Human trichinosis is caused by consumption of meat containing encysted larvae of *Trichinella spiralis*, a tissue-dwelling nematode with a worldwide distribution. After ingestion of raw or inadequately cooked meat containing viable *Trichinella* larvae, the organisms are released from the cyst by acid-pepsin digestion of the cyst walls in the stomach and then pass into the small intestine. The larvae invade the small intestine columnar epithelium at the villi base and develop into adult worms. The adult female produces about 500 larvae over 2 wk and is then expelled in the feces. The larvae seed striated muscle via the bloodstream and burrow into individual muscle fibers. Over a period of 3 wk, they coil as they increase about 10 times in length and become capable of infecting a new host if ingested. The larvae eventually become encysted and can remain viable for years.

Epidemiology.

Despite veterinary public health efforts to control and eradicate the parasite, reemergence of the disease has been observed in many areas of the world in the past 10–20 yr. Trichinosis is most common in Asia, Latin America, and Central Europe. Swine fed with garbage may become infected when given uncooked trichinous scraps, usually pig meat, or when the carcasses of infected wild animals such as rats are eaten. Prevalence rates of *T. spiralis* in domestic swine range from 0.001% in the United States to 25% or greater in China. The recent resurgence of this disease can be attributed to translocations of animal populations, human travel, and export of food as well as ingestion of sylvatic *Trichinella* through game meat. Most outbreaks occur from the consumption of *T. spiralis*–infected pork (or horse meat in areas of the world where horse is eaten) obtained from a single-source.

Pathogenesis.

During the first 2–3 wk after infection, pathologic reactions to infection are limited to the gastrointestinal tract and include a mild, partial villous atrophy with an inflammatory infiltrate of neutrophils, eosinophils, lymphocytes, and macrophages in the mucosa and submucosa. Larvae are released by female worms and disseminate over the next several weeks. Skeletal muscle fibers show the most striking changes with edema and basophilic degeneration. The muscle fiber may contain the typical coiled worm, the cyst wall derived from the host cell, and the surrounding lymphocytic and eosinophilic infiltrate.

Clinical Manifestations.

The development of symptoms depends on the number of viable larvae ingested. Most infections are asymptomatic or mild. Diarrhea is the most common symptom corresponding to maturation of the adult worms in the gastrointestinal tract, which occurs during the first 1–2 wk after ingestion. Patients may also complain of abdominal discomfort and vomiting. Fulminant enteritis may develop in individuals with extremely high worm burdens. The classic symptoms of periorbital edema, fever, and myalgia peak about 2–3 wk after the infected meat is ingested as the larvae encyst in the muscle. Headache, cough, dyspnea, dysphagia, subconjunctival and splinter hemorrhages, and a macular or petechial rash may occur. Patients with high intensities of infection may die from myocarditis, encephalitis, or pneumonia.

Diagnosis.

The Centers for Disease Control and Prevention diagnostic criteria for trichinosis requires positive serology or muscle biopsy for *Trichinella* with one or more compatible clinical symptoms such as eosinophilia, fever, myalgia, and periorbital edema. In a discrete outbreak, at least one person must have positive serology or muscle biopsy. Antibodies to *Trichinella* are detectable about 3 wk after infection. Severe muscle involvement can result in elevated serum creatine phosphokinase and lactic dehydrogenase levels. Muscle biopsy is not usually necessary, but if needed, a sample should be obtained from a tender swollen muscle. A history of eating undercooked meat supports the diagnosis.

Treatment.

Mebendazole (200–400?mg tid PO for 3 days then 400–500?mg tid PO for 10 days for all ages) should be administered to eradicate the adult worms if a patient has ingested contaminated meat within the previous week. An alternative regimen is albendazole (400?mg bid PO for 8–14 days for all ages). There is no consensus for treatment of muscle-stage trichinosis. Systemic corticosteroids with mebendazole may be used, although evidence for their efficacy is anecdotal. A recent study demonstrated that both thiabendazole (25?mg/kg bid PO for 10 days) and mebendazole (200?mg bid PO for 10 days) are effective against muscle larvae although mebendazole may have been less active but thiabendazole was poorly tolerated.

Prevention.

Trichinella larvae can be killed by cooking meat (55°C or more) until there is no trace of pink fluid or flesh, or storage in a freezer (-15°C) for 3 weeks or longer. Smoking, salting, and drying meat are unreliable methods of killing *Trichinella*. Strict adherence to pubic health measures can reduce infection with *Trichinella*. These measures include following garbage feeding regulations, stringent rodent control,

prevention of exposure of pigs and other livestock to animal carcasses, constructing barriers between livestock, wild animals, and domestic pets, and proper handling of wild animal carcasses by hunters.

Chapter 277 - Schistosomiasis (Schistosoma)

Charles H. King

Etiology.

Schistosoma organisms are the flukes, or trematodes, that parasitize the bloodstream. Five schistosome species infect humans: *Schistosoma haematobium, S. mansoni, S. japonicum, S. intercalatum,* and *S. mekongi.* Humans are infected through contact with water contaminated with **cercariae**, the free-living infective stage of the parasite. These motile, forked-tail

organisms emerge from infected snails and are capable of penetrating intact human skin. In the subcutaneous tissues, cercariae change into the next developmental stage, the **schistosomula**, and migrate to the lungs and finally the liver. As they reach sexual maturity, adult worms migrate to specific anatomic sites characteristic of each schistosome species: *S. haematobium* adults are found in the perivesical and periureteral venous plexus, *S. mansoni* in the inferior mesenteric, and *S. japonicum* in the superior mesenteric veins. *S. intercalatum* and *S. mekongi* are found in the mesenteric vessels. Adult schistosome worms (1–2?cm long) are clearly adapted for an intravascular existence. Unlike the other flukes, *Schistosoma* organisms are diecious, and the two sexes are dissimilar in appearance. The female accompanies the male in a groove formed by the lateral edges of its body. On fertilization, female worms begin oviposition in the small venous tributaries. The eggs of the three main schistosome species have characteristic morphologic features: *S. haematobium* has a terminal spine, *S. mansoni* has a lateral spine, and *S. japonicum* has a smaller size with a short, curved spine (Fig. 277–1). Eggs reach the lumen of the urinary tract or intestines and are carried to the outside environment, where they hatch if deposited in fresh water. Motile **miracidia** emerge; they infect specific freshwater snail intermediate hosts and divide asexually. In 4–6 wk, the infective cercariae are released in the water.

Epidemiology.

Schistosomiasis infects >200 million people worldwide, primarily children and young

adults. Prevalence is increasing in many areas as population density increases and new irrigation projects provide broader habitats for vector snails. Humans are the definitive host for the five clinically important species of schistosomes, although *S. japonicum* may infect some animals such as dogs and cattle. *S. haematobium* is prevalent in Africa and the Middle East; *S. mansoni* in Africa, the Middle East, the Caribbean, and South America; and *S. japonicum* in China, the Philippines, and Indonesia, with some sporadic foci in parts of Southeast Asia. The other two species are less prevalent. *S. intercalatum* is found in West and Central Africa, and *S. mekongi* is found in the Far East.

Transmission depends on disposal of excreta, the presence of specific intermediate snail hosts, and the patterns of water contact and social habits of the population. The distribution of infection in endemic areas shows that prevalence increases with age to a peak at 10–20 yr of age. Measuring intensity of infection (by quantitative egg count in urine or feces) demonstrates that the

Figure 277-1 Eggs of *Schistosoma haematobium (A), Schistosoma mansoni (B),* and *Schistosoma japonicum (C)* (×320).

heaviest worm loads are found in the younger age groups. Schistosomiasis, therefore, is most prevalent and most severe in children and young adults, who are at maximal risk of suffering from its acute and chronic sequelae.

Pathogenesis.

The early manifestations of schistosomiasis are immunologically mediated. Acute schistosomiasis, Katayama fever, is a febrile illness that represents an immune complex disease associated with early infection and oviposition. The major pathology of infection is with chronic schistosomiasis, in which retention of eggs in the host tissues is associated with chronic granulomatous injury. Eggs may be trapped at sites of deposition (urinary bladder, ureters, intestine) or be carried by the bloodstream to other organs, most commonly the liver and less often the lungs and central nervous system. The host response to these eggs involves local as well as systemic manifestations. The cell-mediated immune response leads to granulomas composed of lymphocytes, macrophages, and eosinophils that surround the trapped eggs and add significantly to the degree of tissue destruction. Granuloma formation in the bladder wall and at the ureterovesical junction results in the major disease manifestations of schistosomiasis haematobia: hematuria, dysuria, and obstructive uropathy. Intestinal as well as hepatic granulomas underlie the pathologic sequelae of the other schistosome infections: ulcerations and fibrosis of intestinal wall, hepatosplenomegaly, and portal hypertension due to presinusoidal obstruction of blood flow. Protective immunity against schistosomiasis has been demonstrated in some animal species and may occur in humans.

Clinical Manifestations.

Most infected individuals suffer no apparent ill health; symptoms occur mainly in those who are heavily infected. Cercarial penetration of human skin may result in a papular pruritic rash known as **schistosomal dermatitis** or **swimmer's itch**. It is more pronounced in previously exposed individuals and is characterized by edema and massive cellular infiltrates in the dermis and epidermis. Acute schistosomiasis, **Katayama fever**, may occur, particularly in heavily infected individuals 4–8 wk after exposure; this is a serum sickness–like syndrome manifested by the acute onset of fever, chills, sweating, lymphadenopathy, hepatosplenomegaly, and eosinophilia. Acute schistosomiasis most commonly presents in first-time visitors to endemic areas who experience primary infection at an older age.

Symptomatic children with chronic schistosomiasis haematobia usually complain of frequency, dysuria, and hematuria. Urine examination shows erythrocytes, parasite eggs, and occasional leukocytes. In endemic areas, moderate to severe pathologic lesions have been demonstrated in the urinary tract of >50% of infected children. The extent of disease correlates with the intensity of infection, but significant morbidity can occur even in lightly infected children. The terminal stages of schistosomiasis haematobia are associated with chronic renal failure, secondary infections, and cancer of the bladder.

Children with chronic schistosomiasis mansoni, japonica, intercalatum, or mekongi may have intestinal symptoms; colicky abdominal pain and bloody diarrhea are the most common. The intestinal phase may, however, pass unnoticed, and the syndrome of hepatosplenomegaly, portal hypertension, ascites, and hematemesis may be the initial presentation. Liver disease is due to granuloma formation and subsequent fibrosis; no appreciable liver cell injury occurs, and hepatic function may be preserved for a long time. Schistosome eggs may escape into the lungs, causing pulmonary hypertension and cor pulmonale. *S. japonicum* worms may migrate to the brain vasculature and produce localized lesions that cause seizures. Transverse myelitis rarely has been reported in children or young adults with chronic *S. haematobium* or *S. mansoni* infection.

Diagnosis.

Schistosome eggs are found in the excreta of infected individuals; quantitative methods should be used to provide an

indication of the intensity of infection. For diagnosis of schistosomiasis haematobia, a volume of 10?mL of urine should be collected around midday, which is the time of maximal egg excretion, and filtered for microbiological examination. Stool examination by the Kato thick smear procedure is the method of choice for diagnosis and quantification of other schistosome infections.

Treatment.

Treatment of children with schistosomiasis should be based on an appreciation of the intensity of infection and the extent of disease. The recommended treatment for schistosomiasis is praziquantel (40?mg/kg/24?hr divided bid for 1 day for schistosomiasis haematobia, mansoni, and intercalatum; 60?mg/kg/24?hr divided tid for 1 day for schistosomiasis japonica and mekongi).

Prevention.

Transmission in endemic areas may be decreased by reducing the parasite load in the population. The availability of oral, single-dose, effective chemotherapeutic agents may help achieve this goal. Other measures, particularly improved sanitation and focal application of molluscicides, may be useful. Control of schistosomiasis is closely linked to economic and social development.

Chapter 278 - Flukes (Liver, Lung, and Intestinal)

Charles H. King

Several different **trematodes**, or **flukes**, can parasitize humans and cause disease. Flukes are endemic worldwide but are more prevalent in the less developed parts of the world. They include *Schistosoma*, the blood flukes (Chapter 277), as well as fluke species that cause infection in the human biliary tree, lung tissue, and intestinal tract. These latter trematodes are characterized by their complex life cycles. Sexual reproduction of adult worms in the definitive host produces eggs that are passed in the stool. Larvae, called **miracidia**, develop in fresh water. These, in turn, infect certain species of molluscs (snails or clams), in which asexual multiplication by parasite larvae produces **cercariae**. Cercariae then seek a second intermediate host such as an insect, crustacean, or fish or attach to vegetation to produce infectious **metacercariae**. Humans acquire liver, lung, and intestinal fluke infections by eating uncooked, lightly cooked, pickled, or smoked foods containing these infectious parasite cysts. The “alternation of generations” requires that flukes parasitize more than one host (often three) to complete their life cycle. Because parasitic flukes are dependent on these nonhuman species for transmission, the distribution of human fluke infection closely matches their ecologic range.

LIVER FLUKES

Fascioliasis (*Fasciola hepatica*).

Fasciola hepatica, the **sheep liver** fluke, infects cattle, other ungulates, and occasionally humans. Infection has been reported in many different parts of the world, particularly South America, Europe, Africa, China, Australia, and Cuba. Although *F. hepatica* is enzootic in North America, reported cases are extremely rare. Humans are infected by ingestion of metacercariae attached to vegetation, especially wild watercress. In the duodenum, the parasites excyst and penetrate the intestinal wall, liver capsule, and parenchyma. They wander for a few weeks before entering the bile ducts, where they mature. Adult *F. hepatica* (1 × 2.5?cm) commence oviposition approximately 12 wk after infection; the eggs are large (75 × 140?µm) and operculated. They pass to the intestines with bile and exit the body in the feces (Fig. 278–1). On reaching fresh water, the eggs mature and hatch into miracidia, which infect specific snail intermediate hosts to multiply into many cercariae. These then emerge from infected snails and encyst on aquatic grasses

and plants.

Clinical manifestations usually occur either during the liver migratory phase of the parasites or after their arrival at their final habitat in bile canaliculi. Fever, right upper quadrant pain, and hepatosplenomegaly characterize the first phase of illness. Peripheral blood eosinophilia is usually marked. As the worms enter bile ducts, most of the acute symptoms subside. On rare occasions, patients may suffer from obstructive jaundice or biliary cirrhosis. *F. hepatica* infection is diagnosed by identifying the characteristic eggs in fecal smears or duodenal aspirates.

Bithionol (30–50?mg/kg once daily PO on alternate days for a total of 10–15 doses) is the recommended treatment. In the United States, bithionol is available from the Centers for Disease Control and Prevention (telephone: 404-639-3670). The investigational drug triclabendazole (Ciba-Geigy) may also be used to treat fascioliasis.

Clonorchiasis (*Clonorchis sinensis*).

Infection of bile passages with *Clonorchis sinensis,* the **Chinese or oriental liver fluke**, is endemic in China, other parts of East Asia, and Japan. Humans acquire infection by ingestion of raw or inadequately cooked freshwater fish carrying the encysted metacercariae of the parasite under their scales or skin. Metacercariae excyst in the duodenum and pass through the ampulla of Vater to the common bile duct and bile capillaries, where they mature into hermaphroditic adult worms (3 × 15?mm). *C. sinensis* worms deposit small operculated eggs (14 × 30?µm), which are discharged by way of the bile duct to the intestine and feces (see Fig. 278–1). The eggs mature and hatch outside the body, releasing motile miracidia into local

Figure 278-1 Eggs of liver flukes. *A, Fasciola hepatica* (× 400). *B, Clonorchis sinensis* (×1,000). *C,* A lung fluke, *Paragonimus westermani* (×400).

freshwater streams, rivers, or ponds. If these are ingested by the appropriate snails, they develop into cercariae, which are in turn released from the snail to encyst under the skin or scales of freshwater fish.

Most individuals with *C. sinensis* infection, particularly those with few organisms, are asymptomatic. In heavily infected individuals, who tend to be older (>30 yr of age), localized obstruction of a bile duct results from repeated local trauma and inflammation. In these cases, cholangitis and cholangiohepatitis may lead to liver enlargement and jaundice. In Hong Kong, Korea, and other parts of Asia, cholangiocarcinoma is associated with chronic *C. sinensis* infection.

Clonorchiasis is diagnosed by examination of feces or duodenal aspirates for the parasite eggs. The recommended treatment of clonorchiasis is praziquantel (75?mg/kg/24?hr divided tid PO for 1 day). An alternative, used in adults, is albendazole (10?mg/kg once daily PO for 7 days).

Opisthorchiasis (*Opisthorchis*).

Infections with species of *Opisthorchis* are clinically similar to those by *C. sinensis*. *O. felineus* and *O. viverrini* are liver flukes of cats and dogs that infect humans through ingestion of metacercariae in freshwater fish. Infection with *O. felineus* is endemic in Eastern Europe and Southeast Asia, and *O. viverrini* is found mainly in Thailand. Most individuals are asymptomatic; liver enlargement, relapsing cholangitis, and jaundice may occur in heavily infected individuals. Diagnosis is based on recovering eggs from stools or duodenal aspirates. The recommended treatment of opisthorchiasis is praziquantel (75?mg/kg/24?hr divided tid PO for 1 day).

LUNG FLUKES

Paragonimiasis (*Paragonimus*).

Human infection by the **lung fluke** *Paragonimus westermani,* and less frequently other species of *Paragonimus,* occurs throughout the Far East, in localized areas of West Africa, and in several parts of Central and South America. The highest incidence of paragonimiasis occurs in older children and adolescents 11–15 yr of age. Although *P. westermani* is found in many carnivores, human cases are relatively rare and seem to be associated with specific dietary habits, such as eating raw freshwater crayfish or crabs. These crustaceans contain the infective metacercariae in their tissues. After ingestion, the metacercariae excyst in the duodenum, penetrate the intestinal wall, and migrate to their final habitat in the lungs. Adult worms (5 × 10?mm) encapsulate within the lung parenchyma and deposit brown operculated eggs (60 × 100?µm), which pass into the bronchioles and are expectorated by coughing (see Fig. 278–1). Ova can be detected in the sputum of infected individuals or in their feces. If eggs reach fresh water, they hatch and undergo asexual multiplication in specific snails. The cercariae encyst in the muscles and viscera of crayfish and freshwater crabs.

Most individuals infected with *P. westermani* harbor low or moderate worm loads and are asymptomatic. The *clinical manifestations* include hemoptysis, which is the principal manifestation and occurs in 98% of symptomatic children, cough, and production of rust-colored sputum. There are no characteristic physical findings, but laboratory examination usually demonstrates marked eosinophilia. Chest radiography often reveals small patchy infiltrates or radiolucencies in the middle lung fields; however, the radiograph may appear normal in one fifth of infected individuals. In rare circumstances, lung abscess, pleural effusion, or bronchiectasis may develop. Extrapulmonary localization of *P. westermani* in the brain, peritoneum, intestines, or pleura may rarely occur. Cerebral paragonimiasis is encountered primarily in heavily infected individuals living in highly endemic areas of the Far East; the clinical presentation resembles jacksonian epilepsy or cerebral tumors.

Definitive diagnosis of paragonimiasis is established by identification of eggs in fecal or sputum smears. The recommended treatment of paragonimiasis is praziquantel (75?mg/kg/24?hr divided tid PO for 2 days).

INTESTINAL FLUKES

Several wild and domestic animal intestinal flukes, such as *Fasciolopsis buski, Nanophyetus salmincola,* and *Heterophyes heterophyes,* may accidentally infect humans. *F. buski* is endemic in the Far East. Humans who ingest metacercariae encysted on aquatic plants become infected. These develop into large flukes (1 × 5?cm) that inhabit the duodenum and jejunum. Mature worms produce operculated eggs that pass with feces; the organism completes its life cycle through specific snail intermediate hosts. Individuals with *F. buski* infection are usually asymptomatic; heavily infected subjects complain of abdominal pain and diarrhea and show signs of malabsorption. Diagnosis of fasciolopsiasis and other intestinal fluke infections is established by fecal examination and identification of the eggs. As for other fluke infections, praziquantel (75?mg/kg/24?hr divided tid PO for 1 day) is the drug of choice.

Chapter 279 - Adult Tapeworm Infections

Ronald Blanton

Infections with **cestodes**, or **tapeworms**, are prevalent on every continent except Antarctica. Unlike many parasites that strictly segregate their developmental stages in different host species, some tapeworms can infect humans with the adult worm stage, the invasive intermediate stage, or both. The intermediate stages of some tapeworms, such as with cysticercosis (Chapter 280) and echinococcosis (Chapter 281), are invasive and form cystic structures that produce tissue damage from mass effect or inflammatory reactions. No signs or symptoms can clearly be attributed to infection with any adult tapeworm except for *Diphyllobothrium latum*. Infection with the adult worm can be easily diagnosed by finding eggs or segments of adult worms in the stool, whereas the invasive stage of the parasite cannot be observed in any easily sampled fluid. Infection with an intermediate stage, therefore, must be diagnosed by serologic tests, imaging, or invasive procedures.

TAENIASIS (*TAENIA SAGINATA* AND *TAENIA SOLIUM*)

Etiology.

The **beef tapeworm**, *T. saginata*, and the **pork tapeworm**, *T. solium*, are large parasites (4–10?m) named for their intermediate hosts. The adult stages are only found in the human intestine. The body of the adult stage is a connected series of hundreds or thousands of flattened segments, called **proglottids**,

whose most anterior segment, the **scolex**, anchors the parasite to the bowel wall. New segments arise at the caudal end of the scolex followed by progressively more mature ones. The gravid terminal segments are each packed with 50,000–100,000 eggs, and the eggs or these intact proglottids pass in the stool. These two tapeworms differ most significantly in that the intermediate stage of the pork tapeworm (cysticercus) can also infect humans and cause significant morbidity (Chapter 280).

Epidemiology.

Both *Taenia* species are distributed worldwide, with the highest risk of infection in Central America, Africa, India, Southeast Asia, and China. The prevalence in adults may not reflect the prevalence in young children, because cultural practices may dictate how well meat is cooked and how much is served to children.

Pathogenesis.

Uncomplicated infection with the adult beef or pork tapeworm by itself is an infrequent source of symptoms. When children ingest raw or undercooked infected meat, gastric acid and bile facilitate release of the immature scolex that attaches to the lumen of the small intestine. The parasite adds new segments, and after 2–3 mo the terminal segments mature and become gravid.

Clinical Manifestations.

Adult beef and pork tapeworms cause very little overt morbidity apart from nonspecific abdominal symptoms. The proglottids of these tapeworms are visually striking. They are also motile and sometimes produce anal pruritus. They can often be felt as they pass and are thus likely to be noticed and cause a strong emotional reaction in older children and parents when discovered. The adult beef and pork tapeworms are rare causes of intestinal obstruction, cholangitis, and appendicitis.

Diagnosis.

It is important to identify the infecting species of tapeworm. Carriers of adult pork tapeworms are at increased risk of transmitting eggs with the pathogenic intermediate stage (cysticercus) to themselves or others, whereas children infected with the beef tapeworm are a risk only to livestock. Because proglottids are generally passed intact, visual examination for gravid proglottids in the stool is a sensitive test; these segments may be used to identify species. Eggs, by contrast, are often absent from stool and cannot reliably distinguish between *T. saginata* and *T. solium* (Fig. 279–1). If the parasite is completely expelled, the scolex of each species is diagnostic. The scolex of *T. saginata* has only a set of four anteriorly oriented suckers, whereas *T. solium* is armed with a double row of hooks in addition to suckers. The proglottids of *T. saginata* have more than 20 uterine branches from a central uterine structure, and those of *T. solium* have 10 or fewer. When in doubt, more proglottids should be obtained or the sample should be referred to a laboratory with parasitologic expertise.

Figure 279-1 Eggs of *Taenia saginata* recovered from feces (×400). The eggs are generally bile-stained, dark, and prismatic. There is occasionally some surrounding cellular material from the proglottid in which the egg develops, which is more evident in *B* than in *A*. The larva within the egg show three pairs of hooklets *(A),* which may occasionally be seen in motion.

DIFFERENTIAL DIAGNOSIS.

Anal pruritus may mimic symptoms of pinworm (*Enterobius vermicularis*) infection. *D. latum* or even *Ascaris lumbricoides* might be mistaken for *T. saginata* or *T. solium* in stools.

Treatment.

Infections with all adult tapeworms respond to praziquantel (5–10?mg/kg PO once), which is the recommended treatment for taeniasis. Praziquantel tends to cause parasite death and subsequent resorption unless purged. An alternative treatment is niclosamide (50?mg/kg PO once for children, 2g PO once for adults). The parasite is usually expelled on the day of administration.

Prevention.

Prolonged freezing or thorough cooking of beef and pork kills the parasite. Appropriate human sanitation can interrupt transmission by preventing infection in livestock.

DIPHYLLOBOTHRIASIS (*DIPHYLLOBOTHRIUM LATUM*)

Etiology.

The **fish tapeworm**, *D. latum,* is the longest human tapeworm (10–20?m) and has an organization similar to that of other adult cestodes. An elongated scolex equipped with slits, called **bothria**, along each side, but no suckers or hooks, is followed by thousands of segments looped in the small bowel. The terminal gravid proglottid detaches periodically but tends to disintegrate before expulsion, thus releasing its eggs into the feces. In contrast to taeniids, the life cycle of *D. latum* requires two intermediate hosts. Eggs hatch in fresh water and release embryos that are swallowed by small crustaceans (copepods). The parasite passes up the food chain as small fish eat the copepods and are in turn eaten by larger fish. In this way, the juvenile parasite becomes concentrated in pike, walleye, perch, salmon, and similar fish. Consumption of raw or undercooked fish leads to human infection with adult fish tapeworms.

Epidemiology.

The fish tapeworm is most prevalent in the temperate climates of Europe, North America, and Asia but may be found in cold lakes at high altitudes in South America and Africa. In North America, the prevalence is highest in Alaska, Canada, and the northern United States, and the tapeworm is found in fish from those areas brought to market in the continental United States. Persons who prepare raw fish for home or commercial use or who sample fish before cooking are particularly at risk for infection.

Pathogenesis.

The adult worm efficiently scavenges vitamin B_{12} for its own use in the constant

production of large numbers of segments and as many as 1 million eggs per day. The parasite also inhibits vitamin B_{12} uptake by uncoupling the B_{12} -intrinsic factor complex. As a result, diphyllobothriasis causes megaloblastic anemia in 2–9% of infections. Children with other causes of vitamin B_{12} or folate deficiency such as chronic infectious diarrhea, celiac disease, or congenital malabsorption are more likely to develop symptomatic infection.

Clinical Manifestations.

Infection is largely asymptomatic except in those who develop B_{12} or folate deficiency. Megaloblastic anemia with leukopenia, thrombocytopenia, glossitis, and signs of spinal cord posterior column degeneration (loss of vibratory sense, proprioception, and coordination) can be evidence of advanced nutritional deficiency due to diphyllobothriasis. The hematologic and neurologic signs may present independently or as a cluster.

Diagnosis.

Parasitologic examination of the stool is useful because eggs are abundant in the feces and have a morphology distinct from that of all other tapeworms. The eggs are ovoid and have an operculum, which is a cap structure at one end that opens to release the embryo (Fig. 279–2). The worm itself has a distinct scolex and proglottid morphology; however, these are not likely to be passed spontaneously.

DIFFERENTIAL DIAGNOSIS.

A segment or a whole section of the worm might be confused with *Taenia* or *Ascaris* after it is

Figure 279-2 Eggs of *Diphyllobothrium latum* as seen in feces (×400). The caplike operculum is at the upper end of the egg here.

passed. Pernicious anemia, bone marrow toxins, and dietary restrictions may contribute to or mimic diphyllobothriasis.

Treatment.

Infections with all adult tapeworms respond to praziquantel (5–10?mg/kg PO once), which is the recommended treatment for diphyllobothriasis.

Prevention.

The intermediate stage is easily eliminated by brief cooking or prolonged freezing. Because humans are the major reservoir for adult worms, health education is one of the most important tools for preventing transmission, together with improved human sanitation.

HYMENOLEPIASIS (*HYMENOLEPIS*)

Infection with *Hymenolepis nana*, the dwarf tapeworm, is very common in developing countries. It is a major cause of eosinophilia, and although it rarely causes overt disease, the presence of *H. nana* eggs in stool may serve as a marker for exposure to poor hygienic conditions. Although the intermediate stage develops in various hosts (rodents, ticks, and fleas), the entire life cycle can be completed in humans. Hyperinfection with thousands of small adult worms in a single child is thus a potential. Less commonly, a similar infection may occur with the species *H. diminuta.* Eggs but not segments may be found in the stool. *H. nana* infection responds to praziquantel (25?mg/kg PO once) or niclosamide (1?g PO for children 11–34?lb, 1.5?g PO for =35?lb for 6 days).

DIPYLIDIASIS (*DIPYLIDIUM CANINUM*)

Dipylidium caninum is a common tapeworm of domestic dogs and cats, yet human infection is relatively rare. Direct transmission between pets and humans does not occur; human infection requires ingestion of the parasite's intermediate host, the dog or cat flea. Infants and small children are particularly susceptible because of their level of hygiene, generally more intimate contact with pets, and activities in areas where fleas can be encountered. Eosinophilia may occur, but no symptoms clearly result from infection. Anal pruritus, vague abdominal pain, and diarrhea have at times been associated with dipylidiasis. Dipylidiasis may be confused with pinworm (*E. vermicularis*). Dipylidiasis is effectively treated with praziquantel (5–10?mg/kg PO once) or niclosamide (1?g for 11–34?lb, 1.5?g for =35?lb PO once). Deworming pets and flea control are the best preventive measures.

Chapter 280 - Cysticercosis

Ronald Blanton

Etiology.

Cysticercosis is caused by infection with the intermediate stage of *Taenia solium*, the **pork tapeworm**, and is the most common and serious parasitic infection of the central nervous system (CNS). Unlike the beef tapeworm (see Chapter 279), the intermediate stage of *Taenia solium* is infectious for humans and preferentially invades the CNS, causing **neurocysticercosis**. Whereas consumption of infected undercooked pork produces intestinal infection with the adult worm, humans acquire the intermediate form by ingestion of food or water contaminated with the eggs of *T. solium.* Cysticercosis may, therefore, develop even in individuals who do not eat pork. Individuals infected with an adult *T. solium* may infect themselves with the eggs by the fecal-oral route. Reverse peristalsis in the small intestine has also been implicated as a means of autoinfection.

In the small intestine, the egg releases an **oncosphere** that crosses the gut wall and spreads hematogenously to many tissues, primarily brain and muscle. Wherever the eggs lodge, they produce small (0.2–0.5?cm) fluid-filled bladders containing a single **protoscolex**, the juvenile-stage parasite.

Epidemiology.

The pork tapeworm is distributed worldwide wherever pigs are raised. Intense transmission occurs in Central and South America, India, Indonesia, Korea, and China as well as some areas of Africa. In these areas, 20–50% of cases of epilepsy may be due to cysticercosis. Most cases of cysticercosis in the United States are imported; transmission is uncommon but occurs on occasion.

Pathogenesis.

The cystic stages of most tapeworms do not provoke a strong immunologic response while they remain alive and intact. Intact viable cysts can be associated with disease when the initial parasite invasion of the brain is massive or when they obstruct the flow of cerebrospinal fluid (CSF). Most cysts remain viable for 5–10 yr and then begin to degenerate, followed by a vigorous host response. The natural history of cysts is to resolve by complete resorption or calcification.

Clinical Manifestations.

Seizures are the presenting finding in >70% of cases, although any cognitive or neurologic abnormality from psychosis to stroke may be a manifestation of cysticercosis. Neurocysticercosis can be classified as parenchymal, intraventricular, meningeal, spinal, or ocular on the basis of anatomic location, clinical presentation, and radiologic appearance.

Parenchymal neurocysticercosis produces seizures as well as focal neurologic deficits. The seizures are generalized in 80% of cases but frequently begin as simple or complex partial seizures. Rarely, cerebral infarction can result from obstruction of small terminal arteries or vasculitis. With extensive frontal lobe disease, symptoms of intellectual deterioration with dementia or Parkinsonism may obfuscate diagnosis until focal signs appear. A fulminant encephalitis-like presentation also occurs, most frequently in children who have had a massive initial infection. **Intraventricular neurocysticercosis** (5–10% of all cases) is associated with hydrocephalus and acute, subacute, or intermittent signs of increased intracranial pressure without localizing signs. The fourth ventricle is the most common site for obstruction and symptoms; cysts in the lateral ventricles are less likely to cause obstruction. **Meningeal neurocysticercosis** is associated with signs of meningeal irritation and also increased intracranial pressure that results from edema, inflammation, or the presence of a cyst obstructing flow of CSF. Chronic basilar meningitis is associated with many forms of neurocysticercosis, but predominantly meningeal presentations. **Racemose**

neurocysticercosis is a meningeal form of disease in which large, lobulated cysts appear in the basal cisterns. **Spinal neurocysticercosis** presents with evidence of spinal cord compression, nerve root pain, transverse myelitis, or meningitis. **Ocular neurocysticercosis** causes decreased visual acuity due to cysticerci floating in the vitreous, retinal detachment, or iridocyclitis. Outside of the CNS, cysts can sometimes be palpated under the skin, and very heavy infections in skeletal or heart muscle can result in myositis or carditis.

Diagnosis.

Neurocysticercosis should be suspected in any child with any onset of a neurologic, cognitive, or personality disorder and also a history of residence in an endemic area or a care provider from an endemic area. Seizures, hydrocephalus, unilateral visual impairment, or symptoms of encephalitis are particularly suspicious. Proglottids (segments) or eggs are observed in feces from only 25% of cases of neurocysticercosis; therefore, imaging studies and serologic tests are necessary to confirm a clinical suspicion.

The most useful diagnostic study for parenchymal disease is CT. A solitary parenchymal cyst, with or without contrast enhancement, and numerous

calcifications are the most common findings in children (Fig. 280–1). Intraventricular cysts are found in 11–17% of cases of neurocysticercosis. MRI better detects intraventricular cysts as well as those in the spinal cord by delineating parasite membranes and differences in signal intensity between the fluids and tissues of the cysticercus. The protoscolex may even be visible within the cyst by MRI, which provides a pathognomonic sign of cysticercosis. MRI is also more sensitive for detecting evidence of inflammation surrounding a cyst. Plain films may reveal calcifications in muscle or brain consistent with cysticercosis, but these are often nondiagnostic in children.

Serologic diagnosis using the enzyme-linked immunotransfer blot (EITB) is available commercially in the United States and through the Centers for Disease Control and Prevention. Serum antibody testing has >90% sensitivity and specificity; testing of CSF is not required. Persons with many parenchymal cysts almost always have a positive serum EITB test result. Cases with solitary lesions or old calcified disease may not have detectable antibodies. Neurocysticercosis is the most important and most frequent cause of eosinophilia in CSF, but this is not a reliable finding and if absent does not preclude the diagnosis.

DIFFERENTIAL DIAGNOSIS.

Neurocysticercosis can be confused clinically with encephalitis, stroke, meningitis, and many other conditions. Clinical suspicion is based on travel history or a history of contact with an individual who might carry an adult tapeworm. On imaging studies, cysticerci can be difficult to distinguish from tuberculomas, histoplasmosis, blastomycosis, toxoplasmosis, sarcoidosis, vasculitis, and tumor.

Figure 280-1 CT image of a solitary lesion of neurocysticercosis with *(A)* and without *(B)* contrast, showing contrast enhancement. (Courtesy of Dr. Wendy G. Mitchell and Dr. Marvin D. Nelson, Children's Hospital, Los Angeles.)

Treatment.

The specific treatment of neurocysticercosis depends on disease presentation. Many issues concerning whether, when, and how to treat are still not resolved. Observation, symptomatic treatment, antiparasitic drugs, and surgery all may have a role. Children with seizures, no hydrocephalus, and only calcified, inactive lesions on CT do not require therapy other than anticonvulsant medications. If no anticysticercal drugs are administered, however, it is also necessary to determine whether these patients carry adult worms, which poses a public health risk. Niclosamide used in the treatment of adult worms is not absorbed and does not provoke an inflammatory response to cysticerci. Most seizures that are associated with inflammation, as demonstrated by CT or MRI, can be controlled using standard anticonvulsants. If seizures are recurrent or associated with inactive lesions, treatment should be continued for 2–3 yr before attempting weaning from anticonvulsants.

Active parenchymal lesions usually resolve spontaneously, and some experts do not treat with anticysticercal drugs. Some studies indicate, however, that anticysticercal chemotherapy is associated with fewer residual seizures on long-term follow-up. Two effective drugs are available: albendazole (15?mg/kg/24?hr divided bid PO for 28 days; maximum: 800?mg/24?hr) taken with a fatty meal to improve absorption and praziquantel (50–100?mg/kg/24?hr divided tid PO for 30 days). Several studies indicate that albendazole produces a somewhat better outcome than praziquantel. A worsening of symptoms can follow the use of either drug as the host responds to the dying parasite with increased inflammation. Corticosteroids for 2–3 days before and during drug therapy can ameliorate these effects but may decrease praziquantel levels by as much as 50%. An increase of praziquantel (to 100?mg/kg/24?hr divided tid PO) or administration of cimetidine, an inhibitor of the cytochrome P450 system, has been advocated when both praziquantel and corticosteroids are used. Albendazole levels, in contrast, increase in the presence of corticosteroids.

Antiparasitic therapy may convert quiescent parenchymal lesions to active lesions or may worsen ventricular, spinal, or ocular disease. A ventricular shunt must be placed before medical therapy whenever there is evidence of hydrocephalus or ventricular or spinal disease. Surgery should be limited to placement of shunts, removal of large solitary cysts for decompression, removal of mobile cysts causing ventricular obstruction, and some cases that fail to respond to medical therapy. Neuroendoscopy may be used to remove some ventricular cysts. Spillage of cyst contents during surgery is not associated with dissemination of the parasite, in contrast with echinococcosis. Ocular cysticercosis is essentially a surgical disease, although there are reports of cure using medical therapy alone. The outcome is not good in most cases, and enucleation is frequently required. Most treatment options remain controversial and expert consultation is recommended.

Prevention.

All family members of index cases of cysticercosis, as well as persons handling their food, should be examined for signs of disease or evidence of adult worms. Attention to personal hygiene, proper handwashing by food handlers, and avoidance of fresh fruits and vegetables in areas endemic for *T. solium* help prevent ingestion of eggs. All pork should be cooked thoroughly.

Chapter 281 - Echinococcosis (*Echinococcus granulosus* and *E. multilocularis*)

Ronald Blanton

Etiology.

Echinococcosis (**hydatid disease** or **hydatidosis**) is the most widespread, serious human cestode infection in the world. It is a zoonosis that is transmitted from domestic and wild members of the canine family. Two major *Echinococcus* species are responsible for distinct clinical presentations, *E. granulosus* (**unilocular** or **cystic hydatid disease**) and the more malignant *E. multilocularis* (**alveolar hydatid disease**). Dogs, wolves, dingoes, jackals, coyotes, and foxes become infected after eating infected viscera and are the hosts of the small adult worms (2–7?mm). The adult worms are composed of 2–6 proglottids and have a life span of about 5 mo. Eggs from adult worms are passed in stool and contaminate the soil and water, as well as the coats of dogs themselves.

Domestic animals such as sheep, goats, cattle, and camels ingest *E. granulosus* eggs while grazing. Humans are infected with the intermediate stage of the parasite by ingesting food or water contaminated with eggs or by direct contact with infected dogs. The intermediate forms penetrate the gut and are carried by the vascular or lymphatic systems to the liver, lungs, and less commonly to other tissues. A sylvatic cycle also exists for *E. granulosus* in a wolf/moose cycle in North America, but it is of less importance for transmission to humans. The transmission cycle of *E. multilocularis* is similar to that of *E. granulosus,* except that this species is mainly sylvatic and uses small rodents as its natural intermediate host. The rodents are consumed by foxes, their natural predators, and sometimes by dogs and cats.

Epidemiology.

E. granulosus thrives in environments as diverse as arctic tundra and the deserts of North Africa. There is potential for transmission of this parasite to humans wherever animals are herded by humans with the help of dogs. In urban areas, dogs may be infected by eating entrails after home slaughter of domestic animals. Cysts have

been detected in up to 10% of the human population in northern Kenya and Western China. In South America, the disease is prevalent in sheep-herding areas of the Andes, the beef-herding areas of the Brazilian/Argentine Pampas, and Uruguay. Among developed countries, the disease is recognized in Italy, Greece, Portugal, Spain, and Australia. In North America, transmission occurs by way of the sylvatic cycle in Alaska, Canada, and Isle Royale on Lake Superior, as well as in foci of the domestic cycle in sheep-raising areas of the western United States.

Transmission of *E. multilocularis* occurs primarily in temperate climates of Northern Europe, Siberia, Turkey, and China. There is also an extensive area of transmission in Alaska, Canada, and the central United States as far south as Nebraska. Alveolar echinococcosis is, fortunately, uncommon. A separate species, *E. vogeli*, causes polycystic disease similar to alveolar hydatidosis in South America.

Pathogenesis.

In areas endemic for *E. granulosus,* the parasite is often acquired in childhood, but liver cysts require many years to become large enough to detect or cause symptoms. In children, the lungs appear to be the most common site, whereas 70% of adults have disease in the right lobe of the liver. Cysts can also develop in bone, the genitourinary system, bowels, subcutaneous tissues, and brain. The host surrounds the primary cyst with a tough, fibrous capsule. Inside this capsule, the parasite produces a thick lamellar layer that supports a thin germinal layer of cells responsible for production of thousands of juvenile-stage parasites (protoscolices) that remain attached to the wall or float free in the cyst fluid. With cystic hydatidosis from *E. granulosus* infection, the established cyst may also produce smaller daughter cysts that remain contained within the primary cysts. The fluid in a healthy cyst is clear and watery. After medical treatment, it may become thick and bile stained.

Active infection with *E. multilocularis* resembles a malignancy. The secondary reproductive units bud externally and are not confined within a single well-defined structure. Furthermore, the cyst tissues are poorly demarcated from those of the host, which makes these cysts unsuitable for surgical removal. The secondary cysts are also capable of distant metastatic spread of the parasite. The growing cyst mass eventually replaces a significant portion of the liver and compromises adjacent tissues and structures.

Clinical Manifestations.

The majority of cysts occur in the liver. Many cysts never become symptomatic and regress spontaneously. Those that become symptomatic initially have relatively nonspecific symptoms. Later, increased abdominal girth, hepatomegaly, a palpable mass, vomiting, or abdominal pain ensues. The more serious complications, however, result from compression of adjacent structures, spillage of cyst contents, and location of cysts in sensitive areas such as the reproductive tract, brain, and bone. Anaphylaxis can occur with cyst rupture or spillage of cyst fluid intraoperatively. Spillage can be catastrophic, in that each protoscolex can form a new cyst. Jaundice due to cystic hydatid disease is rare. The second most common site is the lung, where cysts produce chest pain, coughing, or hemoptysis. Bone cysts may cause pathologic fractures, and in the genitourinary system they can produce hematuria or infertility.

In alveolar hydatid disease, cyst tissue continues to proliferate and may separate and metastasize distantly. The proliferating mass compromises hepatic tissue or the biliary system and causes progressive obstructive jaundice and hepatic failure. Symptoms also occur from expansion of extrahepatic foci.

Diagnosis.

On physical examination, subcutaneous nodules, hepatomegaly, or a palpable abdominal mass may be found. The parasite cannot be recovered from any easily accessible body fluid unless a lung cyst ruptures, after which protoscolices may briefly be seen in sputum. Ultrasonography has proved a very valuable tool in the diagnosis of hydatid disease. Portable machines and generators have made office diagnosis or survey of even isolated populations possible. Benign, simple cysts of the liver are relatively common, but the presence of internal membranes and floating echogenic cyst material (hydatid sand) strongly suggests hydatid disease. Alveolar disease is less cystic in appearance and resembles a diffuse solid tumor. CT findings (Fig. 281–1) are similar to those of ultrasonography and can at times be useful in distinguishing alveolar from cystic hydatid disease in geographic regions where both occur.

Serologic studies can be useful in confirming a diagnosis of echinococcosis, but the false-negative rate may be as high as 50% in cystic hydatid disease of the lungs or when only young, intact liver cysts are present. Most patients with alveolar hydatidosis, however, develop detectable antibody responses. Current tests use crude or partially purified antigens that can cross react in individuals infected with other parasites, such as in cysticercosis or schistosomiasis.

DIFFERENTIAL DIAGNOSIS.

Cystic hydatid disease can usually be distinguished from benign hepatic cysts on ultrasonography by the presence of either internal structures or hydatid sand. The density of bacterial hepatic abscesses is distinct from the watery cystic fluid characteristic of *E. granulosus* infection, but hydatid cysts may be complicated by secondary bacterial infection. Alveolar echinococcosis is often confused

Figure 281-1 CT image of a hepatic *Echinococcus granulosus* hydatid cyst. The membranes of multiple internal daughter cysts are visible within the primary cyst structure. (Courtesy of Dr. John R. Haaga, University Hospitals, Cleveland, Ohio.)

with hepatoma and cirrhosis and presents features suggestive of pancreatic carcinoma, metastatic liver disease, and cholangitis.

Treatment.

Hydatidosis is still primarily a surgical disease. For *E. granulosus* disease, open surgical procedures are rapidly being replaced by ultrasound- or CT-guided *p*ercutaneous *a*spiration, *i*nstillation of hypertonic saline or another scolicidal agent, and *r*easpiration (PAIR) after 15?min. Spillage with PAIR is surprisingly uncommon, but prophylactic albendazole therapy is recommended. At present, PAIR is appropriate for small simple cysts of the liver, but larger more complicated cysts, lung cysts, and renal cysts have been successfully treated. Cysts found to have bile-stained fluid should not be injected with a scolicidal agent because toxicity is increased.

For conventional surgery, the inner cyst wall (laminate and germinal layers) can be easily peeled from the fibrous layer, and only these inner layers need be removed. The cavity is then topically sterilized and either closed or filled with omentum. Considerable care must be taken to avoid spillage of cyst contents, because cyst fluid contains viable protoscolices, each capable of producing secondary cysts wherever it lodges. An additional risk is development of anaphylaxis to spilled cyst fluid as a result of surgery, spontaneous rupture, or trauma.

For *E. granulosus* cysts not amenable to PAIR or surgery, albendazole (15?mg/kg/24?hr divided bid PO for 1–6 mo; maximum: 800?mg/24?hr) is the preferred drug for treatment. A positive response occurs in 40–60% of patients. There are few adverse effects except for occasional mild gastrointestinal disturbance and elevated transaminases on prolonged use. Morbid inflammatory response to chemotherapy is not common, as it is in cysticercosis, and corticosteroids thus are not indicated unless patients have anaphylaxis or another allergic response. Ultrasonographic indications of successful therapy are a change in shape from spherical to elliptic or flat, progressive increase in echogenicity, and detachment of membranes from the capsule (water lily sign). Additional CT criteria are reduction in diameter and augmented density of cyst fluid up to that of other tissues.

Alveolar hydatidosis is frequently incurable by any modality, but radical surgery such as partial hepatectomy or lobectomy may cure early limited disease. Medical therapy with albendazole may slow the progression of alveolar hydatidosis, but if at all feasible, removal of the infected tissue is indicated.

Prognosis.

Factors predictive of success with chemotherapy are age of the cyst (<2 yr), low internal complexity of the cyst, and small size. The site of the cyst is not important, although cysts in bone respond poorly. For alveolar hydatidosis, if surgical removal is successful, the average mortality is 92% by 10 yr after diagnosis.

Prevention.

Important measures to interrupt transmission include, above all, thorough handwashing, avoiding contact with dogs in endemic areas, boiling or filtering water when camping, proper disposal of animal carcasses, and proper meat inspection. Strict procedures for proper disposal of refuse from slaughterhouses must be instituted and followed so that dogs or wild carnivores do not have access to entrails. Other useful measures are control or treatment of the feral dog population and regular praziquantel treatment of pets and working dogs in endemic areas.

Chapter 282 - Immunization Practices

Georges Peter

Immunization is a remarkably successful and very cost-effective means of preventing infectious diseases and is one of the leading achievements of public health and pediatrics. As a result of routine childhood immunizations, the occurrence of once common contagious diseases declined markedly in the United States and other countries in the second half of the 20th century. Public health programs based on vaccination have led to global eradication of smallpox, elimination of wild-type polioviruses from the Americas and likely from the world in the near future, and more than 95% reduction in the United States of invasive *Haemophilus influenzae* type b (Hib) disease. In addition, congenital rubella syndrome, tetanus, and diphtheria have been nearly eliminated and the incidence of rubella and measles has been reduced to record low rates in the United States.

Infants and children in the United States routinely receive vaccines against 11 diseases: diphtheria, tetanus, pertussis, poliomyelitis, measles, mumps, rubella, Hib infection,

pneumococcal infection, hepatitis B, and varicella. Hepatitis A and influenza vaccines are recommended for some groups of children.

DEFINITIONS AND GENERAL CONCEPTS

Vaccination is administration of any vaccine or **toxoid** (inactivated toxin) for prevention of disease. **Immunization** is the process of inducing immunity artificially by either vaccination **(active immunization)** or administration of antibody **(passive immunization).** Active immunization involves stimulating the immune system to produce antibodies and cellular immune responses that protect against the infectious agent. Passive immunization provides temporary protection through administration of exogenously produced antibody, such as immune globulin. Passive immunization also occurs naturally through transplacental transmission of antibodies to a fetus, which provides protection against many infectious diseases for the first several months of the infant's life.

Immunizing agents include vaccines, toxoids, antitoxins, and immune globulins derived from human or animal donors (Table 282–1); more than 50 immunobiologic products are licensed in the United States. Immune globulins for passive immunization now can be prepared from monoclonally produced antibody. Most immunizing agents contain preservatives, stabilizers, antibiotics, adjuvants, and a suspending fluid (Table 282–2).

The current approaches to active immunization are the use of (1) live-attenuated infectious agents and (2) inactivated or detoxified agents, their extracts, or specific recombinant products (e.g., hepatitis B vaccine). For many diseases, such as poliomyelitis and typhoid fever, both approaches have been used. Live-attenuated vaccines are more likely than killed vaccines to induce an immunologic response simulating the response to natural infection. Inactivated or killed vaccines include inactivated whole organisms (e.g., whole-cell pertussis and hepatitis A vaccines), detoxified exotoxins (e.g., tetanus and diphtheria toxoids), purified protein antigens (e.g., acellular pertussis and hepatitis B vaccines), polysaccharides (e.g., capsular meningococcal vaccine), capsular polysaccharides conjugated to carrier proteins (e.g., Hib and pneumococcal conjugate vaccines), and components of the organism (e.g., subunit influenza vaccine).

Organisms in live vaccines multiply in the recipient until the desired immune response occurs, similar to that which occurs in natural infection. Thus, live-attenuated viral vaccines (e.g., measles, rubella, and mumps) are likely to confer lifelong protection with a single immunizing dose. In contrast, many inactivated or killed vaccines, which have a lesser antigenic mass, require booster vaccinations to provide protection.

Determinants of the Immune Response.

Responses of individuals to the same vaccine vary because the immune response to specific

TABLE 282-1 -- Immunizing Agents

Agent	Definition

Vaccine	A preparation of proteins, polysaccharides, or nucleic acids of pathogens that are delivered to the immune system as single entities, as part of complex particles, or by live-attenuated agents or vectors, to induce specific responses that inactivate, destroy, or suppress the pathogen
Toxoid	A modified bacterial toxin that has been made nontoxic but retains the capacity to stimulate the formation of antitoxin
Immune globulin	An antibody-containing solution derived from human blood obtained by cold ethanol fractionation of large pools of plasma and used primarily for the maintenance of immunity of immunodeficient persons or for passive immunization; available in intramuscular and intravenous preparations
Antitoxin	An antibody derived from the serum of humans or animals after stimulation with specific antigens; used to provide passive immunity

TABLE 282-2 -- **Constituents of Vaccines**

Component	Use and Examples
Preservatives, stabilizers, antibiotics	Constituents can inhibit or prevent bacterial growth or stabilize the antigen. Materials such as mercurials or antibiotics are used. Allergic reactions to any of the additives may occur.
Adjuvants	An aluminum salt is used in some vaccines to enhance the immune response (e.g., toxoids, hepatitis B).
Suspending fluid	Sterile water, saline, or more complex fluids derived from the growing media or biologic system in which the agent is produced (e.g., egg antigens, cell culture ingredients, serum proteins).

antigens is genetically determined. The extensive polymorphism of the major histocompatibility complex (MHC) in humans results in recognition by different individuals of different epitopes within a complex protein antigen. To vaccinate a population effectively, a vaccine must contain epitopes that are processed and bound to the product of at least one MHC allele in most individuals.

The nature and magnitude of the response to vaccines or toxoids are determined by many factors, including the chemical and physical state of the antigen, the mode of administration, the catabolic rate of the antigen, host factors (e.g., age, nutrition, gender, and pre-existing antibody), and antigen processing as well as the genetic determinants of the host. The age-dependent differences in immune responses are a critically important consideration in the routine immunization schedule of infants and young children. The presence of high concentrations of maternal antibody in the first few months of life and the relative immaturity of the immune response impair the initial immune response to some vaccines.

The route of administration is another important factor in the immune response. Parenterally administered vaccines may not induce mucosal secretory IgA, whereas vaccines given orally are likely to do so. The immunogenicity of some vaccines is reduced when not given by the proper route. For example, subcutaneous administration of hepatitis B vaccine into the fatty tissue of the buttock of adults rather than intramuscularly in the deltoid results in substantially lower seroconversion rates.

Immune Response to Vaccine Antigens.

Antibodies produced in response to vaccine constituents may be of any immunoglobulin class. Important protective antibodies include those that inactivate soluble toxic protein products of bacteria (i.e., antitoxins), facilitate phagocytosis and intracellular digestion of bacteria (i.e., opsonins), interact with components of serum complement to damage the bacterial membrane with resultant bacteriolysis (i.e., lysins), prevent proliferation of infectious virus (i.e., neutralizing antibodies), and interact with components of the bacterial surface to prevent adhesion to mucosal surfaces (i.e., antiadhesins). Antibodies function alone or in conjunction with other components of the immune system by participating directly in the neutralization of a

toxin (e.g., diphtheria); opsonization of virus (e.g., poliovirus); initiating or combining with complement and promoting phagocytosis (e.g., pneumococcus); reacting with nonsensitized lymphocytes to stimulate phagocytosis; or sensitizing macrophages to stimulate phagocytosis.

Many of the structural constituents of microorganisms and exotoxins are antigenic. Most antigens require the interaction of B lymphocytes and T lymphocytes to generate an immune response and, thus, are termed T (thymus)-dependent antigens. However, some antigens initiate B-cell proliferation and antibody production without the help of T cells and, thus, are T-independent antigens. In contrast to T-dependent antigens, most T-independent antigens are poor immunogens in children younger than 2 yr of age. Because many purified polysaccharides

are T-independent antigens, vaccines composed of these antigens are often ineffective in infants and young children. Examples include the first generation of Hib and pneumococcal vaccines. By conjugation to a protein carrier, however, a polysaccharide can acquire the antigenic properties of the protein and resulting characteristics of a T-dependent antigen, including immunogenicity in infants. This phenomenon is the basis of the development of Hib and pneumococcal conjugate vaccines. Meningococcal conjugate vaccines also have been developed and are now available in several countries, including Great Britain and Canada.

Induction of a T-dependent antibody response initially requires activation of T-helper (CD4) lymphocytes by presentation of an antigen to mononuclear phagocytes or dendritic cells, a process that may be facilitated by an adjuvant. Antigen presentation triggers the secretion of a cascade of mediators, called cytokines, which stimulate the maturation of naive T-helper cells and communication between leukocytes, using interleukins to regulate the immune response.

In the primary response to a vaccine antigen, a latent period of several days elapses before humoral and cell-mediated immunity can be detected. Serum antibodies initially are detected usually 7–10 days or more after vaccination. The immunoglobulin class of the response evolves and varies with the type of antigen. The initial antibodies are usually IgM; subsequent antibodies are usually IgG. The early IgM and IgG antibodies are secreted by B lymphocytes in response to T-dependent antigens. IgM antibodies are detectable first and fix complement, which facilitates lysis and phagocytosis of microorganisms. The IgM titer diminishes and the IgG titer rises during the 2nd wk or later. IgG responses peak within 2–6 wk. The change from IgM synthesis to predominately IgG synthesis in B lymphocytes requires T-lymphocyte cooperation. IgG antibodies are produced in high concentrations and are critical to resistance to infections. Their functions include affinity to microorganisms, viral neutralization, precipitation of antigens, and fixation of complement.

Live-virus vaccines given orally (e.g., oral poliovirus and investigational influenza) replicate at mucosal surfaces before host invasion and induce secretory IgA at respiratory, gastrointestinal, and other local sites. IgA antibodies neutralize viruses efficiently, fix complement through the alternative pathway, prevent absorption of organisms to the intestinal wall, and lyse gram-negative bacteria with complement and lysozyme. Most other types of vaccines do not effectively induce secretory IgA antibodies.

Heightened humoral or cell-mediated responses are elicited by a second exposure to the same T-dependent antigen. Secondary responses occur rapidly and usually within 4–5 days, result from immunologic memory mediated by T and B lymphocytes, and are characterized by a marked proliferation of antibody-producing B lymphocytes or effector T lymphocytes. However, T-independent antigens such as purified polysaccharide vaccines do not evoke these heightened secondary immune responses.

The response to vaccines in clinical practice is assessed by the serum concentration of specific antibody. The presence of circulating antibodies usually correlates with protection, and for some vaccines (e.g., tetanus, diphtheria, and Hib) the specific antibody titers that correlate with protection have been established. However, antibody seroconversion and concentrations are only one parameter of the host response. Cellular immunity also is important but is much more difficult to measure and to correlate with protection. Amnestic responses on revaccination, which indicate immunologic memory, suggest that immunity may be persistent. Accordingly, the lack of detectable serum antibody may not mean that the individual is unprotected, particularly with infections that have a long incubation period, such as hepatitis B.

Stimulation of the immune system by vaccination, independent of antibody production, may elicit unanticipated responses, especially hypersensitivity reactions. For example, killed measles vaccine induced incomplete humoral immunity and cell-mediated hypersensitivity, resulting in the development of a syndrome of atypical measles (see Chapter 225) in some children after subsequent infection by wild-type virus.

VACCINE RECOMMENDATIONS

Many factors are considered in the development of recommendations and schedules for vaccine administrations, including the epidemiology of the disease, age-specific morbidity and mortality, vaccine immunogenicity, risks of vaccine-related adverse reactions, cost effectiveness, and the ages of recommended routine health care visits. In general, vaccines for universal administration to children are recommended at the youngest age at which significant risk of disease and its complications exist and at which a protective immunologic response can be expected. Other vaccines are recommended only in special circumstances, such as for children at increased risk for infection during foreign travel (e.g., typhoid vaccine), those at increased risk of severe infections (e.g., pneumococcal polysaccharide vaccine for children with sickle cell disease), and those after exposure (e.g., rabies vaccine in children bitten by a potentially rabid animal).

In the United States, recommendations for childhood immunization are formulated by two committees, the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) and the American Academy of Pediatrics (AAP) Committee on Infectious Diseases. These two committees and the American Academy of Family Physicians (AAFP) issue an annual national schedule

for routinely recommended childhood vaccinations.

Vaccines for Routine Use in Children and Adolescents.

All children should be vaccinated against diphtheria, tetanus, pertussis, poliomyelitis, measles, mumps, rubella, Hib, *Streptococcus pneumoniae*, hepatitis B, and varicella unless contraindicated (Fig. 282–1). As of 2002, completion of this schedule by 18 mo of age necessitates 16–20 injections in four to five visits. However, introduction of new combination vaccine is anticipated in the near future and will reduce the number of injections for routine vaccine administration.

The first dose of hepatitis must be given at birth to infants of hepatitis B surface antigen (HBsAg)-positive mothers for optimal prevention of maternal-fetal viral transmission (see Chapter 339). All infants should receive the first dose soon after birth and before hospital discharge, but it also may be given in the first 2 mo of life if the mother is HBsAg negative.

For poliomyelitis immunization in the United States, inactivated poliovirus vaccine (IPV) now is recommended to eliminate the risk of vaccine-associated paralytic poliomyelitis associated with oral poliovirus vaccine (OPV). The recommended regimen for IPV, which is the same as that for OPV, is 2, 4, and 6–18 mo and 4–6 yr of age. OPV, if available, is indicated for unvaccinated children who will be traveling within 4 wk to areas where polio is endemic. OPV remains the vaccine of choice for global eradication of poliomyelitis and is recommended for areas with continued or recent circulation of wild-type poliovirus, most developing countries because of its lower cost than IPV, and areas with inadequate sanitation that necessitate an optimal mucosal barrier to wild-type virus circulation.

Acellular pertussis vaccine, combined with diphtheria and tetanus toxoids (DTaP), is now the recommended vaccine for pertussis immunization in the United States and many countries in Europe. Whole-cell pertussis vaccine, although no longer available in the United States, is still routinely given in many areas, including the United Kingdom and developing countries. After the 7th birthday, combined tetanus and diphtheria toxoids in the adult formulation (Td), which contains a lesser amount of diphtheria toxoid, are recommended for both primary and booster

Figure 282-1 Recommended childhood and adolescent immunization schedule, United States, 2003. [1] **Hepatitis B vaccine (HepB)**. All infants should receive the first dose of hepatitis B vaccine soon after birth and before hospital discharge; the first dose may also be given by age 2 mo if the infant's mother is HBsAg-negative. Only monovalent HepB can be used for the birth dose. Monovalent or combination vaccine containing HepB may be used to complete the series. Four doses of vaccine may be administered when a birth dose is given. The second dose should be given at least 4 wk after the first dose, except for combination vaccines which cannot be administered before age 6 wk. The third dose should be given at least 16 wk after the first dose and at least 8 wk after the second dose. The last dose in the vaccination series (third or fourth dose) should not be administered before age 6 mo. Infants born to HBsAg-positive mothers should receive HepB and 0.5 mL Hepatitis B Immune Globulin (HBIG) within 12 hr of birth at separate sites. The second dose is recommended at age 1–2 mo. The last dose in the vaccination series should not be administered before age 6 mo. These infants should be tested for HBsAg and anti-HBs at 9–15 mo of age. Infants born to mothers whose HBsAg status is unknown should receive the first dose of the HepB series within 12 hr of birth. Maternal blood should be drawn as soon as possible to determine the mother's HBsAg status; if the HBsAg test is positive, the infant should receive HBIG as soon as possible (no later than age 1 wk). The second dose is recommended at age 1–2 mo. The last dose in the vaccination series should not be administered before age 6 mo. [2] **Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP)**. The fourth dose of DTaP may be administered as early as age 12 mo, provided 6 mo have elapsed since the third dose and the child is unlikely to return at age 15–18 mo. **Tetanus and diphtheria toxoids (Td)** is recommended at age 11–12 yr if at least 5 yr have elapsed since the last dose of tetanus and diphtheria toxoid-containing vaccine. Subsequent routine Td boosters are recommended every 10 yr. [3] ***Haemophilus influenzae* type b (Hib) conjugate vaccine**. Three Hib conjugate vaccines are licensed for infant use. If PRP-OMP (PedvaxHIB® or ComVax® [Merck]) is administered at ages 2 and 4 mo, a dose at age 6 mo is not required. DTaP/Hib combination products should not be used for primary immunization in infants at ages 2, 4 or 6 mo, but can be used as boosters following any Hib vaccine. [4] **Measles, mumps, and rubella vaccine (MMR)**. The second dose of MMR is recommended routinely at age 4–6 yr but may be administered during any visit, provided at least 4 wk have elapsed since the first dose and that both doses are administered beginning at or after age 12 mo. Those who have not previously received the second dose should complete the schedule by the 11–12 yr old visit. [5] **Varicella vaccine**. Varicella vaccine is recommended at any visit at or after age 12 mo for susceptible children, i.e., those who lack a reliable history of chickenpox. Susceptible persons aged =13 yr should receive two doses, given at least 4 wk apart. [6] **Pneumococcal vaccine**. The heptavalent **pneumococcal conjugate vaccine (PCV)** is recommended for all children age 2–23 mo. It is also recommended for certain children age 24–59 mo. **Pneumococcal polysaccharide vaccine (PPV)** is recommended in addition to PCV for certain highrisk groups. See *MMWR* 2000;49(RR-9);1–38. [7] **Hepatitis A vaccine**. Hepatitis A vaccine is recommended for children and adolescents in selected states and regions, and for certain high-risk groups; consult your local public health authority. Children and adolescents in these states, regions, and high-risk groups who have not been immunized against hepatitis A can begin the hepatitis A vaccination series during any visit. The two doses in the series should be administered at least 6 months apart. See *MMWR* 1999;48(RR-12);1–37. [8] **Influenza vaccine**. Influenza vaccine is recommended annually for children age =6 mo with certain risk factors (including but not limited to asthma, cardiac disease, sickle cell disease, HIV, diabetes, and household members of persons in groups at high risk; and can be administered to all others wishing to obtain immunity. See *MMWR* 2002;51(RR-3);1–31). In addition, healthy children age 6–23 mo are encouraged to receive influenza vaccine if feasible because children in this age group are at substantially increased risk for influenza-related hospitalizations. Children aged =12 yr should receive vaccine in a dosage appropriate for their age (0.25 mL if age 6–35 mo or 0.5 mL if aged =3 yr). Children aged =8 yr who are receiving influenza vaccine for the first time should receive two doses separated by at least 4 wk. This immunization schedule is updated annually. The current recommended schedule is available at www.nelsonpediatrics.com. For additional information about vaccines, including precautions and contraindications for immunization and vaccine shortages, please visit the National Immunization Program Website at *www.cdc.gov/nip* or call the National Immunization Information Hotline at 800-232-2522 (English) or 800-232-0233 (Spanish).

vaccination. The first booster dose of Td is recommended at 11–12 yr of age and is followed by boosters at 10-yr intervals thereafter.

The 7-valent pneumococcal polysaccharide-protein conjugate vaccine (PCV-7) is routinely recommended for all children 2–23 mo of age in a four-dose schedule at 2, 4, 6, and 12–15 months of age. It also is recommended for older children, 24–59 mo of age, at high risk of invasive pneumococcal infection, such as those with sickle cell disease, asplenia, or HIV infection who have not previously been immunized.

The second dose of measles-containing vaccine (given as measles-mumps-rubella

[MMR]) should be routinely given before school entry at 4–6 yr of age.

Varicella vaccine is recommended beginning at 12 mo of age and for older children through 12 yr of age if they have not been previously immunized or if they lack a reliable history of chickenpox.

Annual influenza vaccination of all children 6–23 mo of age is encouraged, when feasible. Vaccination also is encouraged for their household contacts and out-of-home caretakers, and particularly for contacts of infants younger than 6 mo of age. Influenza vaccine is not indicated for these infants because of inadequate immunogenicity. Children 0–23 mo of age are at substantially increased risk for influenza-related hospitalizations. Routine influenza immunization of all young children may be recommended in the near future.

Hepatitis A vaccine is recommended at 24 mo of age in states and regions with an increased incidence of disease. A second dose is administered 6–12 mo later to complete the series.

To enhance the delivery of vaccines to adolescents, a routine visit at 11–12 yr of age has been established for administration of the first Td booster and, if not already immunized, for hepatitis B and varicella vaccination and the second dose of MMR if not previously administered.

Simultaneous Administration of Multiple Vaccines.

Most vaccines can be given simultaneously without impairment of effectiveness or safety. Simultaneous administration of vaccines is particularly important for inadequately immunized children to ensure timely completion of the recommended schedule. New combination products facilitate administration of multiple vaccines by reducing the number of necessary injections.

Interchangeability of Vaccine Products.

Vaccines made by different manufacturers but directed against the same infections are generally considered interchangeable for the primary series and recommended booster doses. Because data are limited on the safety, immunogenicity, and efficacy of different DTaP vaccines, the same product should be used, whenever feasible, in the pertussis vaccination schedule. However, in circumstances in which the specific DTaP product received previously is not known or the previously administered product is not readily available, any licensed product may be used. Vaccination should not be deferred in these situations.

Lapsed Immunizations.

In general, intervals between vaccine doses that exceed those that are recommended do not adversely affect the immunologic response, provided the immunization series is completed. Hence, restarting the immunization series or giving additional doses is not indicated under these circumstances.

Vaccines with Selective Indications.

Vaccines with selected indications for children include influenza, pneumococcal polysaccharide, hepatitis A, meningococcal polysaccharide, rabies, and those given primarily for international travel.

Influenza vaccine should be given annually in the fall to those children 6 mo of age or older who are at increased risk for severe influenza disease or its complications. Major risk factors are asthma and other chronic pulmonary diseases (e.g., cystic fibrosis), congenital heart disease, HIV infection, other immunosuppressive disorders and therapy, sickle cell disease, and aspirin therapy. Vaccination also should be considered for children with diabetes mellitus, other chronic metabolic disorders, and chronic renal disease and for those traveling to foreign countries where influenza may be occurring.

Pneumococcal polysaccharide vaccine is a 23-valent formulation with limited but important indications for children with sickle cell disease, functional or anatomic asplenia, nephrotic syndrome, renal failure, HIV infection, or organ transplants. It is given in addition to routine PCV-7 immunization. Because the polysaccharide vaccine is composed of T-independent antigens, it is not given until 2 yr of age. A single revaccination is recommended 3–5 yr later if the child remains at increased risk of severe or frequent infections. For older children who were initially immunized 5 yr or more before, revaccination also is indicated.

Meningococcal polysaccharide quadrivalent vaccine is recommended for children 2 yr of age or older who are at increased risk of infection. Indications include functional or anatomic asplenia, terminal complement component or properdin deficiency, travel to geographic areas where disease is hyperendemic or epidemic, and for control of outbreaks as determined by public health officials. Vaccination also should be considered for students entering college, especially those students who will be living in dormitories. These students and their parents should be informed about the increased risk of meningococcal disease in college freshman living in dormitories and the potential benefits of immunization. Vaccine should be made available both by their physician and by college and university health services and may be required by some states. Other college students, although not at increased risk, also may be immunized if they desire.

International travel is a common indication for many vaccines that are not otherwise routinely given to children, because of increased risk of exposure to the diseases. For children living in North America, vaccines for travel may include hepatitis A, typhoid fever, meningococcal disease, yellow fever, and Japanese encephalitis, depending on the location and circumstances of the travel (see Chapter 285). In addition, children and adolescents before departure should have received all routinely recommended vaccines for their age. The risk of exposure to cases of measles may be substantial in some countries. Hence, the second dose of measles vaccine, given as MMR, should be given to children and adolescents who have received only one dose irrespective of age, provided an interval of 4 wk or more has elapsed since the first dose. Influenza vaccine should be considered for children traveling to areas where influenza outbreaks are occurring. Some countries may

require yellow fever vaccination for entry.

ADVERSE EVENTS AFTER VACCINATION

Modern vaccines, although safe and effective, can be associated with adverse events ranging in severity from mild to life threatening. In addition, because no vaccine can be expected to be completely effective, some persons may develop disease after exposure despite vaccination.

Vaccine components can cause allergic reactions in some recipients. These components include the protective antigens, other components of the microorganisms, animal proteins introduced during vaccine production, antibiotics and other preservatives, or stabilizers such as gelatin. Reactions may be local or systemic, including anaphylaxis and urticaria. Local or systemic reactions result from too frequent administration of some vaccines, such as tetanus toxoids or rabies, and are probably caused by antigen-antibody complexes.

Some adverse events, however, occur coincidentally in temporal association with vaccination and are not caused by the vaccine. Determination of causality of an adverse event in a single child may be difficult. Epidemiologic and related studies are necessary to ascertain the incidence and nature of adverse

reactions to vaccines and are important in ensuring a scientific rationale for vaccine recommendations. The decision to use a vaccine involves assessment of the risk of disease, the benefit of vaccination, and the risk associated with vaccination. Continued reassessment of vaccine indications and safety is necessary. Precautions and contraindications are based on these factors, which may be modified with new information. Physicians delivering vaccines should be knowledgeable about indications, vaccine risks, and parental and public misconceptions about alleged vaccine-related adverse events.

PRECAUTIONS AND CONTRAINDICATIONS

Knowledge of vaccine contraindications and precautions is an important aspect of immunization practice (Table 282–3). A precaution specifies a circumstance in which a vaccine may be indicated if the benefit to an individual is judged to outweigh the risk and consequences of an adverse event. In contrast, a contraindication indicates that the vaccine should not be administered. Applying valid contraindications and precautions helps to minimize the occurrence of adverse reactions and maintain the health of children. Deciding not to vaccinate a child because of an inappropriate contraindication or precaution denies the child the benefit of immunization and is a missed opportunity for vaccination.

Generic contraindications to vaccination are an anaphylactic reaction to a previous dose of the same vaccine and an anaphylactic reaction to a vaccine constituent, such as egg proteins, gelatin, or an antibiotic. Viral vaccines that contain egg proteins, associated with vaccine production using embryonated chicken
